

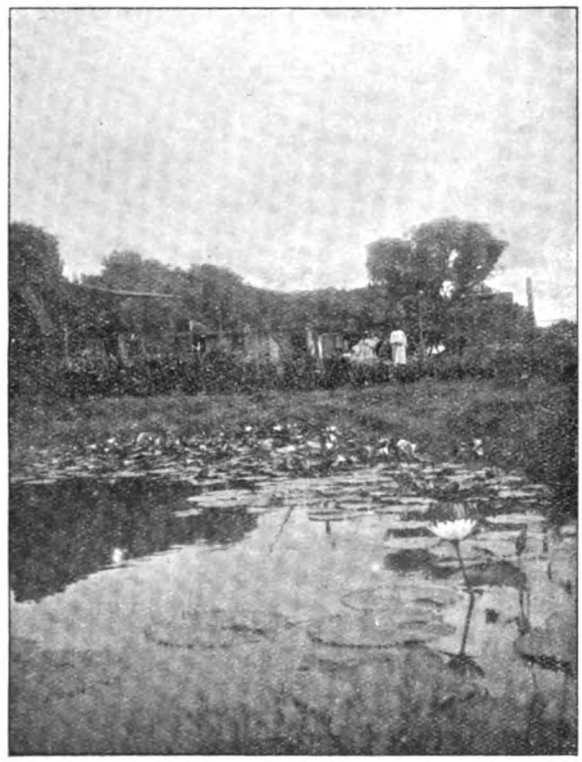

FIG. 3.—A Sydenham Pool (infested) showing blue lotus in flower.

I remember my surprise, in visiting a hospital where I had been asked to treat a typical case of bilharzia disease, to find the urine reported free from sugar, blood or albumin. On another occasion a fellow officer of the S. A. Medical Corps asked me to see a case of his of whom he had already obtained three negative reports for ova in the urine. On each occasion the failure to note the abnormality was due to the urine having been collected from a chamber—an article of furniture which medical men who appreciate the value of keeping the bed-room air sweet throughout the night should do their best to discourage. Personally I attribute little importance to a negative report except where the last ounce or so is passed direct into a separate bottle or large test-tube ready for centrifugalization. One practitioner told me he seldom if ever failed to find the eggs in a bilharzia patient, and it was his practice to persuade the natives to squeeze out the last few drops of urine. A practitioner is hardly justified in undertaking to treat a case of bilharzia unless he is able to follow the degenerative changes that are taking place in the ova passed throughout the series of injections he is giving. The number of incompletely cured cases that are being sent back to their homes is regrettable; for they tend to foster the impression that the disease cannot be cured and they are perhaps more liable to the formation of renal calculus, chronic appendicitis and exploratory operations for vague symptoms, than even the untreated case of bilharzia disease.

Dr. E. C. Faust has pointed out that the discovery of ova resembling those of *Schistosoma bovis* and *S. spindalis* in certain persons harbouring *S. hæmatobium*, or of *S. hæmatobium* and *S. mansoni*, does not necessarily mean that *S. bovis* and *S. spindalis* attack cattle and goats in South Africa, and, since the regrettable departure of Mr. R. E. Montgomery, F.R.C.V.S., from the Union, I do not think that any serious attempts have been made to determine how far schistosomiasis exists in South African mammals. In infested localities there is almost certainly a preponderance of the commoner schistosomes; but I am hoping that amongst some fifty adult worms that I obtained from cercariæ obtained from *I. africana* in a pool which contains both *S. hæmatobium* and *S. bovis*, may be examples of the rarer worm. The ova of this latter parasite would appear to be identical with those found in the urine of some children in the Belgian Congo by Dr. C. C. Chesterman.

The occasional presence of a schistosome in any host must not be regarded as sure evidence of that parasite becoming common in that host, and, although *Fasciola hepatica* does occasionally occur in Australian rabbits, the occurrence would not appear to be so common as to regard the rabbit as a constant source of fasciola infestation to sheep and oxen in that country.

A poor white at Durban, aged about 12 years, showed the ova of *S. hæmatobium*, *S. mansoni* and *S.? bovis* in his urine a year ago. Though his brother was successfully cured by intravenous tartar emetic, he is too little inconvenienced to submit to treatment himself, and three months after I first saw him, when there was much hæmaturia, the urine was almost free from blood and eggs. The problem of the eradication of the disease depends partly on education. As in Egypt, but for a very different reason, the problem is also partly a religious one. The Moslem home is usually provided with a bore hole, and there is no evidence that the disease is spread as a result of their

FIG. 4.—Shells of *Isidora africana* (Krauss).

ablutions; bilharzia disease is rare amongst Natal Moslems, who keep their children away from stagnant pools, as the orthodox Jews avoid all creeping things, including snails. Both Hindus and Christians allow their boys to paddle, fish and swim in the very pools

where the bilharzia parasites are most common, and it is a matter for regret that the Christian Church has set aside certain portions of the Jewish law which are particularly well-suited to the over-crowded life of subtropical villages, with all the inter-breeding and co-mingling of children which such a life necessarily involves. The advantages of abstinence from pork and the discouragement of a meat diet or the indiscriminate use of medicines, as practised in Moslem homes along with the universal rite of circumcision, might well be considered in the interests of those juvenile adults whose temptations are multiplied tenfold by their association with the ever-present menace of the illicit liquor traffic in Natal, and who cannot go out of their houses without passing evidences of defæcation by natives and Hindus along those undrained dongas which daily multitudes use as roads to and from the Durban market.

Ringworm of the Scalp in the Adult. Report of a Case of Kerion due to Microsporon Audouini (H. Fox, *Archives of Dermatology and Syphilology*, March, 1926).—The case described is of interest as an additional record of a rare condition, namely, ringworm of the adult scalp. The lesion, although a kerion, was caused by the *Microsporon audouini*, an organism that is not usually pyogenic. Like the three patients previously studied by the author, this one also belonged to the negro race. It may be added that the culture was made on a Stender dish instead of in the usual flask, no contamination taking place. Numerous other cultures of various species of ringworm have been made on Petri or Stender dishes, without contamination. At least sufficient time has elapsed to allow the cultures to attain full size and to be photographed.

Serological Analysis of Lepers' Sera (O. Schobl and J. Ramirez, *The Philippine Journal of Science*, March, 1926.)—Ninety-two lepers were examined serologically with the view to deciding certain doubtful points in the serology of leprosy. The question of complement and natural hæmolysin content in lepers' sera towards guinea-pig, sheep, goat and rabbit red cells was investigated. The content of hæmolytic complement and its keeping quality in the lepers' sera were studied. anti-sheep and anti-monkey immune hæmolysin having been used in these tests. Slight individual differences were found to exist in lepers' sera and in normal human sera alike as to content of natural hæmolysins and complement, but no distinct quantitative differences were found between the sera of lepers and those of normal persons. The amount of hæmolytic complement in the lepers' sera was found to be the same as that in the sera of non-lepers and is subject to individual variations. As to the keeping quality of the natural hæmolytic complement, it was found that, in proportion to the original titre, the complement decreased practically at the same rate in the sera of lepers as it did in the sera of normal individuals.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments, either** of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—**The Subscription, which is Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these,** with remittance, **is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF

Tropical Medicine and Hygiene

JUNE 15, 1926.

THE RARER BRONCHOMYCOSES.

UNDER the term Bronchomycosis is included all those affections of the bronchi and lungs which are definitely associated with the presence of fungi in

the sputum. Although the monilias constitute the group of fungi which are best known and are found most frequently in this condition, it may in fact be due to quite a variety of fungi belonging to different species, genera, families and orders. No matter which of these different fungi happens to be the causal micro-organism, the symptoms and the disease so produced are somewhat similar, although the prognosis varies considerably according to the variety of the fungus encountered. The varieties of broncho-mycosis caused by fungi other than the monilias are of somewhat rare occurrence, and one of the most important of these is bronchonocardiasis, a name employed to denote all bronchial and broncho-pulmonary affections produced by fungi of the genus *Nocardia*, Toni and Trevisan, and the genus *Cohnistreptothrix*, Pinoy; the latter having perhaps been more commonly known as *Streptothrix*, *Actinomyces*, *Discomyces*, and *Oospora*. The family Nocardiaceæ has been defined as *Microsiphonales* with a mycelium, and contains two genera, namely, *Nocardia*, Toni and Trevisan, 1899, which grows anaerobically, is easy of cultivation, and produces arthrospores, and *Cohnistreptothrix*, Pinoy, 1911, which grows best anaerobically, but can grow aerobically, is difficult of cultivation, and does not produce arthrospores.

Two types of bronchonocardiasis may be differentiated, namely, *granular bronchonocardiasis*, which is often referred to as *actinomycosis bronchialis* or *pulmonalis*, and is characterized by the presence of fungal granules or sclerotia in the sputum, and *agranular bronchonocardiasis*, in which fungal granules or sclerotia are absent from the sputum, and is often referred to as *pseudo-actinomycosis bronchialis* or *pulmonalis*.

Granular bronchonocardiasis or *bronchoactinomycosis* generally runs a chronic course, though acute cases are also occasionally encountered. With regard to symptomatology there is anæmia and wasting with serotine fever. The sputum, at first mucopurulent, is later tinged with blood, and true hæmoptysis may occur. It also contains small granules composed of an enormous number of thin mycelial filaments. Potassium iodide in large doses (30 gr. thrice daily) produces a rapid improvement in this type of nocardiasis, which is much more amenable to treatment than is the agranular type. An autogenous nocardial vaccine has been employed in these cases, but does not seem to produce any definitely beneficial effect.

Agranular bronchonocardiasis, known also as *streptothricosis*, *pseudo-actinomycosis*, and *pseudo-tuberculosis*, constitutes one of the most serious of all the varieties of broncho-mycosis, generally runs a chronic course, though occasionally acute cases are seen. There is anæmia, hæmoptysis, and often serotine fever. Physical examination of the chest may reveal patches of dullness with crepitations and pleural rubbing, or may be quite negative. Microscopic and cultural examination of the sputum is of the utmost importance. Segments of thin bacillary fungi will often be found, showing true but not dichotomous branching, which are sometimes acid-fast. Both aerobic and anaerobic methods of cultivation should be employed as some nocardias (*cohnistreptothrix*) grow only anaerobically. The treatment of this variety of bronchonocardiasis is apt to be disappointing and unsatisfactory. It consists in the oral administration of potassium iodide in big doses, together with the hypodermic injection of autogenous nocardia vaccine. In spite of all treatment many cases end fatally.

Broncho-anaeromycosis is another of the rarer forms of bronchomycosis, and was investigated by Castellani, Douglas and Thompson. It is due to a branching bacillary fungus of the order Microsiphonales, which is not pathogenic to the usual laboratory animals. The fungus has been isolated from a large number of cases of bronchitis of hæmorrhagic and mucopurulent types. Cases of the hæmorrhagic type closely resemble pulmonary tuberculosis; there may be fever of an intermittent or remittent type, the patient becomes anæmic and wasted, the sputum contains blood and may present a very characteristic bright brick-red colour. The physical examination of the chest may show signs which suggest tuberculosis, such as patches of dullness and crepitations.

Broncho-oidiosis is another rare form of bronchomycosis in which the causal fungi belong to the genus *Oidium*, characterized by abundant mycelium with numerous arthrospores. In contrast to the monilias free yeast-like budding cells are absent or rare. Acid, but no gas, is produced in various sugars and other carbohydrates. The genus comprises four species, namely, *Oidium lactis*, Link, 1809, *O. rotundatum*, Castellani, 1911, *O. Asteroides*, Castellani, 1914, and *O. metalense*, Castellani, 1915. Clinically broncho-oidiosis is similar to bronchomoniliasis, and a primary and secondary form are to be distinguished.

Broncho-saccharomycetosis is due to the fungi of the genus *Saccharomyces*. These fungi are characterized by reproduction, by budding, by the absence of a mycelium, and by the presence of asci in old cultures. The symptomatology is like that of bronchomoniliasis.

Broncho-cryptococcosis, which is due to fungi belonging to the genus *Cryptococcus*, is clinically similar, occurring both in primary and secondary forms. These fungi consist of yeast-like budding cells without mycelium, and their cultures never show the presence of asci.

Broncho-endomycosis and *broncho-Williasis* are still other rare bronchomycoses, and present the same symptomatology as chronic bronchomoniliasis. Lastly, there is *Broncho-hemisporosis*, which may be caused by two species of fungus, namely, *Hemispora rugosa*, Castellani, 1910, or *H. pararugosa*, Castellani, Douglas and Thompson, 1923. Here again a mild and a severe type of the affection may be recognized. In the mild type the patient chiefly complains of cough, but the general condition remains good and there is no fever. The sputum is mucopurulent and free from blood. Physical

examination of the chest is negative, or at most reveals only a few coarse râles. The severe type closely resembles phthisis: the patient becomes emaciated, there is hectic fever, and the sputum may contain blood. Physical examination of the chest reveals patches of dullness with fine crepitations and pleural rubbing.

The sheet-anchor in the treatment of all these forms of bronchomycosis is the administration of potassium iodide in big doses, which, except in cases of agranular bronchonocardiasis, usually gives satisfactory results. This may be supplemented by the administration of balsamics, especially creosote. The use of autogenous mycotic vaccines has usually given disappointing results, and they seem to exert little or no beneficial effect on the progress of the disease. F. E. T.

Annotations.

The Nasal Passages in Lobar Pneumonia. A Clinical and Bacteriological Study (A. R. Felty and C. A. Heatley, *Journal of the American Medical Association*, April 17, 1926).—In a series of sixteen cases of lobar pneumonia, pneumococci of corresponding type to those found in the sputum were isolated from the middle fossæ of the nose in every case. The nasal passages in fifteen of the sixteen cases were examined with the nasopharyngoscope; of these, all showed hyperæmia of the mucous membranes, and six had signs of acute suppurative sinusitis. In eight cases anteroposterior roentgenograms of the sinuses were made; in seven cases clouding of one or more of the sinuses was observed. In this small series of cases acute pneumococcal sinusitis was a frequent accompaniment of lobar pneumonia.

Scarlet Fever. An Analysis (J. W. Lindsay, E. C. Rice and M. A. Selinger, *Journal of the American Medical Association*, April 17, 1926).—The intracutaneous injection of properly concentrated scarlet fever toxin, after the method of the Dicks, properly controlled by use in groups, has been found a reliable means of determining susceptibility or immunity to scarlet fever. This method is also frequently of definite assistance in diagnosis. It is possible actively to immunize susceptibles for a considerable period. Care should be used to adjust the dose of toxin for active immunization so as to avoid serious reaction in those who may have an unusually small amount of natural antitoxin, as indicated by an unusually large and intensely positive Dick reaction. There is ample evidence that the serum prepared by the method of Dochez, now available for the treatment of scarlet fever, possesses true and specific antitoxic properties in effective concentrations. The early use of sufficient amounts of antitoxin apparently reduced the incidence of complications of severe degree. A single large dose of antitoxin will probably prove more satisfactory, from every standpoint, than a small or moderate dose with the possibility of repetition. The intramuscular injection appears to be satisfactory in practically all cases, the intravenous possibly being indicated in critical conditions. The authors suggest the advisability of testing all patients for sensitiveness to serum before giving the antitoxin, even though workers are not in complete agreement as to the importance of this procedure.

Gastric and Duodenal Ulcer. Theoretical and Clinical Studies (A. Winkelstein, *Archives of Internal Medicine*, April 15, 1926).—It is seen from these studies that superficial ulcers or erosions of the stomach or duodenum occur owing to various local and general causes, but heal perfectly in most persons. In certain subjects the lesion progresses and takes on the features of chronicity. This is the characteristic of ulcer as a disease entity. The usual explanations, mostly referable to local conditions, for the failure to heal seem incomplete. It is suggested that some general condition, interfering with healing may be present. An excessive response to stimuli on the part of the nerves and tissues, locally or generally, may furnish such interference to healing. Tetany or a related condition, a disturbance of the vegetative nervous system, or a combination of both, are possible causes of the supposed general over-irritability. Patients with ulcer, with gastric neuroses, and controls were tested with various stimuli to ascertain the presence of such over-irritable states. Almost all the ulcer patients respond excessively to mechanical, electrical and pharmacologic stimulation. Patients with gastric neurosis react similarly, except to mechanical stimuli, but present a marked contrast to the ulcer group in that they display obvious stigmas of a disturbed vegetative nervous system. This distinction may prove useful clinically. The persistence of the over-irritability after a surgical cure suggests that it is a general bodily state, probably constitutional, and not merely the result of the presence of the ulcer.

Observations on the White Working Population of Tropical Queensland (R. W. Cilento, *Health*, Commonwealth of Australia, March, 1926).—In estimating the factors that affect working white people in tropical Queensland, the author arrives at conclusions which are extremely satisfactory from the standpoint of future progress, for tropical localities peopled entirely by a white population. Both sexes and all ages were examined, and the results demonstrate that there is no indication that the tropical climate affects the white man deleteriously in any respect *per se*. In making this examination the greatest care was taken to make the most of every disadvantage, and although a large portion of the homes examined were poor, where people live under the most distressing conditions, the high standard of health was still maintained.

The figures laid down demonstrate that the old canard that the white man cannot live in the tropics is definitely exploded. That the white woman cannot live and bear children there is disproved by the excellent figures shown in relation to each of the towns. That these children thrive is similarly evidenced by the statistics throughout the paper; and in their turn they multiply without any loss of fertility, mentality or physique. In fact the whole of the accusations levelled against the tropics are shown by that huge mass experiment which is called the colonization of tropical Queensland to be quite outside the question of climate itself. In the writer's opinion the evil name acquired by the tropics is due almost entirely to facts and figures which have been accepted without a due allowance being made for the tremendous importance of endemic preventable diseases, and a co-resident native population. In the Australian tropics there is neither the one nor the other, and as a consequence these lands are being steadily and progressively peopled by a healthy, working, white population.

Treatment of Neurosyphilis by Malaria. A Preliminary Report (P. O'Leary, W. H. Goeckerman, and S. Parker, *Archives of Dermatology and Syphilology*, March, 1926).—A report is made of the preliminary observations after a ten months' trial of a series of thirty-five patients with neurosyphilis who were inoculated with malaria plasmodia. As this time is too short to draw definite conclusions regarding the value of the procedure the authors have endeavoured merely to relate their experience with it. The method seems to offer more immediate effects than any form of treatment heretofore used for general paralysis. Many of the patients in this group had been treated with tryparsamide, some with benefit and others without. The inoculation of patients with *Plasmodium vivax*, who are already debilitated to some degree from their syphilis, is attended with some risk, so that it is a method for selected patients only who are under hospital care throughout the course. It is only necessary to carry out the procedure with the patient in the hospital from the time of the inoculation until three negative smears have been obtained after the quinine has been started, but measures must be taken also for the prevention of the spread of the malaria to the inhabitants of the community. The dangers of the malaria carriers must be constantly borne in mind, and all attendants must take quinine as a prophylactic during the mosquito time. Of the twenty-four patients with frank paresis, 25 per cent. showed a complete remission that allowed them to return to their former occupations within two months after the malaria was stopped, 37 per cent. were definitely improved one way or another, and two died, one as a result of the malaria and the other six months later in convulsions. Thus far in this series the "fever therapy" has had practically no effect on optic atrophy, gastric crises, persistent lightning pains with negative serologic findings, asymptomatic neurosyphilis and paresis sine paresi. The mental and physical symptoms are most favourably influenced by the treatment without change being observed in the blood or spinal fluid as yet. The use of arsphenamin, mercury or tryparsamide immediately after the malaria was attended with some definite evidence of relapse from remission. The majority of the complications noted were transient and disappeared with the cure of the malaria, although complications attributable directly to the syphilis may cause some embarrassment. Myocarditis, nephritis, marked weakness or wild delirium may demand the cessation of treatment. The results were so encouraging that the authors believe the method warrants an exhaustive trial.

Quantitative Studies of Bacterial Pollution and Natural Purification in the Ohio and the Illinois Rivers (J. K. Hoskins, *U.S. Public Health Reports*, February 19, 1926).—Quite extended observations of the pollution of Illinois and Ohio rivers have indicated that the numbers of bacteria contributed *per capita* by the sewered populations of various cities are reasonably constant; these numbers change, however, with seasonal temperature, being much greater in summer than in winter. Such bacteria tend to increase in numbers in the receiving stream for a short period and then decrease at orderly rates as the time from the point of maximum density is increased. These rates of decrease were found to be affected by water temperature and apparently by concentration, being most intensive during the warmer months and under conditions where the density of bacteria was greatest. Having established definite quantitative relationships from these observations, and assuming that they are fairly representative of stream conditions in general, a method is suggested for estimating the maximum concentration of *Bacillus coli* in streams of unknown volume of flow that may be expected to result from pollution contributed by known sewered populations. Furthermore, the concentration of such organisms remaining at any point downstream may be estimated, providing the velocity of flow is ascertained. If the observations are representative of general biological laws, they are of practical value for estimating the increasing burden placed on streams receiving the sewage of growing communities and, consequently, the added loads that water-purification plants must be prepared to handle where such polluted watercourses are used as sources of water supply.

Erythema Multiforme (E. L. McEwen, *Archives of Dermatology and Syphilology*, March, 1926).—The relationships made apparent by the author and the fact that the symptom which first caused the patient concern was a skin eruption suggest two lines of inquiry. The first is, what is the part actually taken by systemic infection

in skin diseases, particularly by the slowly progressive and initially mild types which may be grouped under the term septicæmia lenta? It is being demonstrated more and more conclusively that organisms within the body, by the products of their metabolism or disintegration, and by mechanical action are responsible directly or indirectly for numerous and varied symptom groups, many of which, though looked on as disease manifestations, are essentially protective body reactions. Conversely, more and more is the physician justified in assuming that infection, directly or indirectly, is the most probable cause of any symptom group with which he may be dealing. This statement finds confirmation in the conception and increasing acceptance of the idea of focal infection. The skin, by reason of its extent, its structure and its functions, is predestined to be the organ for the expression of a large number of manifestations which must be regarded as body reactions against harmful agencies within. Keeping in mind the fact that infection may produce primary and secondary effects, we are compelled on *a priori* grounds to regard germ action as probably constituting the major element.

A Fever Resembling a Mild Form of Typhus Fever (F. T. Wheatland, *The Medical Journal of Australia*, March 6, 1926).—A fever of about twelve or fourteen days' duration characterized by severe headache and a macular rash on the body and limbs is described. This fever resembles typhus fever, and it is probably identical with that described by Hone in Adelaide. It is not contagious, and is probably transmitted by some ectoparasite associated with the mouse. There is probably a group of diseases resembling typhus fever of which this fever is a member.

Congenital Alopecia (E. A. Oliver, and N. C. Gilbert, *Archives of Dermatology and Syphilology*, March, 1926).—In reviewing the ætiologic factors the following points present themselves. There is presumably a congenital alopecia in two brothers with no antecedent cases in the family as far as the authors can learn. There are no stigmas of atavism as noted by Hyde. One recognizes the possibility of this being secondary to some generalized cutaneous condition acquired after birth. This, however, is not believed to be the case. The first impression, that the condition was due to thyroid deficiency, would have been believed to be confirmed had thyroid medication been used without first determining the metabolic rate. Other endocrine disorders can, it is believed, be ruled out by the absence of any other factors which would be regarded as anomalies of autonomic response or control. Keratosis pilaris, as suggested by Brocq, is, the authors believe, an important factor in the production of this alopecia. The comment of the patient on his improved condition was of interest. When asked to what he attributed the improvement, he said that when he forcibly removed the papules by scrubbing his scalp vigorously, he believed he allowed the hairs to come through. With the improvement in the hair growth there was a corresponding decrease in the keratosis pilaris. As to the ætiology of the keratosis pilaris, the authors have no theory which they can substantiate, but they believe that it is due to some anomaly of intra-uterine development.

Hæmochromatosis and Chronic Poisoning With Copper (E. F. Mallory, *Archives of Internal Medicine*, March 15, 1925).—Evidence is slowly but steadily accumulating in favour of the view that chronic poisoning with copper causes the symptom complex known under the different names of hæmochromatosis, bronzed diabetes and pigment cirrhosis. Copper is an exceedingly useful and indispensable metal in many ways, but it should not be employed where it may come in contact with foods or drinks, especially if they contain acids of any sort, because it is so readily dissolved by many of them. This would exclude its use for cooking utensils of any sort, for shakers of cocktails and acid drinks, and for the worms of the condensers in stills. Its use in pipes for drinking water and for hot water heaters is probably without danger.

Current Literature.

BULLETIN DE LA SOCIÉTÉ DE PATHOLOGIE EXOTIQUE. January 13, 1926.

On the Treatment of Malaria, an Essentially Curable Disease (4th communication) (T. Seguin).—The author has been writing on this subject in the *Bulletin de la Société de Pathologie Exotique* since 1921, but little importance seems to have been given to his theory on the treatment of malaria. He is convinced that quite 100 per cent. of the cases of relapse would be avoided if the patients were treated with large doses of quinine, i.e., a dose of 50 cgm. in the evening, instead of the usual 25 cgm. which are often taken in the morning and *a fortiori* at midday. Attention is also called to the fact that large doses of quinine, instead of causing hæmoglobinuria, as suggested by some authors, has quite the opposite effect on the disease. Hæmoglobinuria occurs only in cases of malaria which have been insufficiently treated. With large doses of quinine, given at night, malaria is completely cured in a few days.

Notes on an Epidemic of Ulceromembranous and Scorbutic Stomatitis (M. Alalou).—These studies were carried out during the epidemic in the region of Mossoul from November, 1917, to April, 1918.

About 40 cases entered hospital daily, of which about twelve were cases of stomatitis. Both the ulceromembranous and scorbutic types were observed, sometimes they were mixed, and there were some cases of noma the mortality of which was about 2 per cent. Among the cases of ulceromembranous stomatitis the majority were gingival, the others were jugal, palatine, or amygdaline. Vincent's amygdalitis was of the classic type. Tincture of iodine, permanganate of potash, neosalvarsan gave unsatisfactory results. The only remedy which proved successful in all forms of the disease was chromic acid crystals.

The Anti-Piroplasmic Campaign in the Government of Petrograd in 1925. *Preliminary Note.* (W. L. Yakimoff).—In the summer of 1925 the Veterinary School of Petrograd undertook a campaign against bovine babesiasis which was prevalent in the districts of Vytegra and Volkhov. 1,040 infected animals were detected; of this number 773 were treated. The products used were ichtargan, protargol, luargol, silver salvarsan, arrhenal, and apiroplasmine. On the whole, good results were obtained showing an average mortality of only 5·9 per cent., against a mortality of 42·9 per cent. in animals not treated. Symptomatic treatment alone is not sufficient.

Apiroplasmine in the Treatment of Bovine Piroplasmosis (W. J. Yakimoff, J. G. Galouzo, W. A. Loukianoff, and M. J. Furikoff).—Apiroplasmine was first prepared by Alessandrini of Rome; it consists of cacodylate of caffeine 30 per cent., benzoinomonocarbonic acid 10 per cent., phenate of sodium 2 per cent. The instructions given with the preparation are: 20 c.c. should be given intravenously, daily, until complete cure is obtained. It was ordered by the Italian Minister of War to be used in equine piroplasmosis. During the antebabesiasis campaign in Petrograd, 1925, this product was not found to be very efficacious.

Ichtargan in the Treatment of Bovine Babesiasis in the North-West of Russia. Preliminary note. (W. L. Yakimoff).—Ichtargan is a mixture of silver and ichthyol. It has long been used in human cases of gonorrhœa and in diseases of the eye. Schmidt was the first to use it in piroplasmosis; it is largely used in Finland. Excellent results were obtained with this remedy in the treatment of babesiasis in Petrograd in 1925. The mortality was only 2·4 per cent. Hæmoglobinuria disappeared in most cases 24 hours after the intravenous injection of ichtargan, and the temperature was lowered in about the same time.

A Case of Leishmania infantum observed in Sienna, Italy. Epidemiologic Remarks. (P. Barbacci).—A fatal case of infantile Leishmaniasis in a child of four is described. It is the first case observed in the province of Sienna. It is not known how the child contracted the disease, but it is quite probable it was at Monaco, where he stayed for six weeks. Infantile Leishmaniasis occurs in nearly all places round the Mediterranean; it also exists in Indo-China and in the south of Russia.

The Action of Tryparsamide on Chronic Trypanosomiasis (F. Van den Branden).—Further investigations confirm the results already published in this Bulletin, on the action of tryparsamide "A63" in the treatment of chronic trypanosomiasis, i.e., that it is superior to any other product used in the treatment of this disease, and that failures are due to the coexistence of nervous syphilis, or to a previous arsenical treatment which has rendered the trypanosomes resistant to arsenicals.

Prescorbutic Pilous Keratosis (Said Djemil).—During the first three months of 1915 a number of soldiers from the Dardanelles entered the Couleli Hospital, Bosphorus, suffering from scurvy. Many of them presented the classical symptoms, but quite a number, when they entered the hospital, showed signs of pilous keratosis with anæmia, lassitude, and rheumatoid pains in the legs. These prescorbutic keratoid lesions are a greyish or dirty-red colour. They surround the root of the hairs on the antero-external part of the leg, they are rarely seen on the thighs, and it is exceptional to see them on the arms. They can easily be scratched off without causing exudation or bleeding. It is sufficient to observe daily the evolution of the keratose to see them take on the form of the typical follicular petechiæ of scurvy.

A Study of Trachoma in Morocco and its Treatment (E. Delanoe). — The author studied trachoma in Morocco for twelve years. The disease is widely spread, especially in the region of Mazagan, at all times of the year; it is frequently seen in adults, but the majority of cases are observed in children. There are more Arab children affected than Jewish, and this is undoubtedly due to the different schools they frequent and their different modes of living. More than half of the old and poor Jews of Mellah are affected with trachoma, and it is only their weekly visits to the hospital which keeps them alive. On the other hand, the children of these diseased people, who frequent the schools and hospital, and are kept under surveillance, are rarely affected. The infant Mussulman population, whose schools have made no hygienic progress for centuries, is heavily infested with trachoma and is a source of constant epidemics. The latent form of trachoma is the most dangerous, from the propagation point of view, as often it is of long duration without inconveniencing the patient. It is only when the seasonal conjunctivitis occurs that the trachoma is detected. A detailed description is given of the clinical symptoms. Several methods of treatment have been tried; chaulmoogra oil has given the best results.

Manifest Action of Cold in Blackwater Fever (H. Chatrieux).—Three cases are reported in which blackwater fever occurred in patients who had suddenly exposed themselves to cold. Their ages were 23, 24, and 34 years respectively. Two of them—one being a European—had never had malaria, the other had apparently had latent malaria but had not been treated.

Original Communications.

SOME ASPECTS OF MALARIA CONTROL.

By Dr. WILLIAM E. DEEKS.

General Manager, Medical Department, United Fruit Company, New York.

IN view of the present state of our knowledge, we may not hope to eradicate malaria in the near future from many localities, but reasonable control measures are possible and some of these deserve consideration.

Malaria has entirely disappeared from many localities in this country where a few years ago it was epidemic. This has been due mainly to the drainage and cultivation of the soil, and consequent destruction of many mosquito breeding places; but seasonal changes and the intelligent application of our knowledge of the transmission, prevention and cure of the disease have also been important factors. It should be emphasized that poverty and ignorance favour the spread of malaria, and that general prosperity and universal education are important influences in its control; for only when they are enlisted can suitable homes be built, sanitary measures maintained and a knowledge of how to avoid the disease acquired by the people. There is no reason, under present conditions, why an intelligent individual should acquire malaria, if he knows how to avoid contracting it, has the proper appliances available for his protection, and makes careful use of them.

Malaria is responsible for about 40 per cent. of the morbidity on the plantations of the United Fruit Company and is, therefore, the most important single factor in lowering the efficiency of labour. Effective efforts directed towards malaria control in any district presuppose a knowledge of local conditions, not only as to the breeding places of anopheles mosquitoes and a study of the most economical means of their destruction, but also regarding the identity of the vector concerned, inasmuch as there is variation of distance in the flights of the different species of anopheles that transmit malaria, and this must be taken into consideration in undertaking sanitary work.

The tropical plantations of the United Fruit Company are located, for the most part, in the coastal areas of low elevation. Rainfall and temperatures in the different plantations for the months of 1923 and 1924 are shown in the subjoined tables.

Jansco[1] states that the mosquito phase of the cycle of the tertian parasites ceases to develop normally when the temperature reaches 61° F., and if development proceeds the mosquito does not become infective. As can be noted from the tables, the temperature and the amount of rainfall on the plantations are favourable for multiplication of mosquitoes and for the exogenous development of the parasite in the mosquito the whole

year round. The rainfall varies considerably in the different countries and from year to year, but, for the most part, is sufficient for purposes of agriculture. Irrigation is necessary only at certain seasons of the year and in some limited areas.

POPULATION.

On a plantation the labouring population consists mainly of negroes, native Indians, and mixtures of these races with European blood. Most of the illiterate people live under primitive conditions, in unscreened houses, though "bed nets" are used by a considerable proportion of the population.

The administrative personnel consists chiefly of imported whites from temperate zones. Many of these were not exposed to malaria infection before employment and, consequently, had developed no immunity to it. They live on the plantations in screened houses under good sanitary conditions.

DISEASES.

The incidence of the diseases occurring on the plantations is fully recorded in the annual reports published by the United Fruit Company. It will be noted that there is some variation in the different countries. The reasons for this probably are to be found in the differences in the physical, mental and racial characteristics of the respective populations, as well as in the local conditions of topography, character of soil, temperature and rainfall.

Thorough investigations relative to the incidence of diseases of the population in the Tela Division, Honduras, have been carried on by Dr. H. C. Clark for the past three years. In addition to this work, malaria surveys also have been made by Dr. M. A. Barber and Mr. Komp of the U.S.P.H.S. As a result of their investigations we have fairly accurate data of the incidence of this disease in this division. Conditions in the other divisions vary somewhat, but from the data obtained in the Tela Division we are able to reach conclusions and draw inferences which are also applicable, for the most part, to the other divisions.

In these surveys the method used was to take a specimen of blood from each individual and to examine it by the "thick-film" method devised by Barber. The findings do not give the actual incidence of the parasitic infection, but a minimum rate of infection only. Undoubtedly, if the blood had been taken on successive days, a greater incidence of infection would have been revealed. In this connection Dr. Clark's findings in 69 autopsies are instructive:—

INCIDENCE OF MALARIA AT AUTOPSY.

(Disregarding the disease causing the death.)

	Cases	
Parasites and pigment, present in	25	78·2 per cent positive
Pigment present in spleen and rib marrow, in	29	
Negative for pigment or parasites, in	15	... 21·7 per cent negative

SAME CASES BEFORE DEATH.

	Per cent.
Positive for malaria	39·1
Negative for malaria	52·1
Died before an examination could be made ...	8 6

These clearly show that examinations of the peripheral blood do not always give positive findings in malaria infections.

The Barber and Komp surveys were made between January 4 and February 4, 1925. During the period November, 1924, to February, 1925, inclusive, the monthly rainfalls were respectively 33·14 in., 11·13 in., 12·45 in. and 16·25 in. This represents the time when we should have our greatest percentage of malaria infection, because of relapses from chronic malaria as a result of wet and exposure, and new infections resulting from great proliferation of mosquitoes. The following table gives the summarized results of this survey:—

TABLE 11.—SUMMARY OF RESULTS IN THE TELA DIVISION.

It will be noted that there is considerable variation in the percentage of infections found in the different camps and units surveyed. As explanatory of this, Dr. Barber makes a brief reference to the local conditions existing in each locality surveyed.

Farms 7 to 14 inclusive are in the Progreso District. This is a new district in the valley of the Ulua River. It contains three large lagoons —probably river-formed—streams, ponds and lesser bodies of water. Some anopheles larvæ were found in them, in rather brief surveys. Many adult anopheles, however, were discovered in the houses in the labourers' quarters located nearest these breeding places.

Farms 20, 25 and 37 are in the Guaymas District. This is also a new district, recently brought under cultivation. A search for adult anopheles throughout the camps yielded only two specimens. None was found in Camp 37. In this district there are several small streams of clear water which are stocked with fish. The rich surface loam is underlaid with a sandy soil, which facilitates rapid absorption of water following heavy rains. Consequently the mosquitoes do not breed freely in this district, but the percentage of malaria infection existing can be accounted for by the fact that these labourers were drawn from other highly-infected districts.

In both the Lantz and Booth Camps the labourers were employed in irrigation and drainage work. These men live in temporary, palm-thatched shacks without walls. In all frontier work similar conditions exist, and malaria is liable to assume epidemic proportions. This can be accounted for probably by primitive living, unusual fatigue, exposure, &c., and the opening up of virgin territory which temporarily provides new sources for mosquito breeding places.

The Dakota, Hicaque and La Fragua Camps are located in older cultivated districts where conditions are more stabilized, although in these there is a high labour turnover.

Garcia's Plant is a private plantation on the Ulua River. The house of Garcia has well-screened verandahs. An examination of the nineteen members of the household proved all to be negative. In his labouring camps, however, of 119 examined, 33 were found positive.

San Juan is a village of Caribs in a grove near the beach. There is swampy ground back of the village. The majority of the houses are palm-leaf thatched. "Bed nets" are used in many cases. As there is practically no other means of protection from mosquitoes, evidently the degree of immunity is high among the Caribs in this village.

New Tela consists of rows of houses between a swampy stream and the sea coast. The entire community is within easy flight distance of anopheles. Those houses that are near the sea are screened, and are occupied principally by a white foreign population. Back of these are rows of houses occupied by coloured people, and near the swamp rows of houses occupied by natives; all of these dwellings are unscreened. Of 48 persons examined in the American School, all were negative; of 39 examined in the coloured school, only one was positive; of 106 adult Hondurasians examined, from the rows of houses nearest the swamps, 21 were positive, and of 26 of their children examined (10 years and under), 7 were positive. The back rows of houses probably served as a mosquito barrier for those farthest from the mosquito breed-

ing grounds. Furthermore, it is probable that the Hondurasians from the mountain regions have not the degree of racial immunity possessed by the negro race.

Adjoining New Tela is Old Tela, a native town, on the sea, at the mouth of the Tela River. The people here live in unscreened houses. Anopheles breeding was found in the immediate vicinity in several places.

Dr. Clark made a resurvey of some of the camps referred to above, as well as several others during the period from May 18 to July 29, 1925. This may be considered as towards the end of the dry season, when the mosquito index is much lower than it is in the winter season. In the Progreso District 742 were examined in 14 camps and 38·2 per cent. were found positive; and in the Guaymas District, of 13 camps surveyed 19·6 per cent. were positive. In the different camps of the division, 2,742 persons were examined and 769 (28·4 per cent.) were found positive; 81 had heavy infections. Of those examined, 1,767 were men, with 26·3 per per cent. of positive findings; 611 women, with positive findings in 25·8 per cent. cases; and 364 children (10 years and under), with positive findings of 40·1 per cent.

It is also of special interest that, in Dr. Clark's surveys, of 2,607 of the native population living in unscreened quarters, 29·1 per cent. were positive; while of 135 non-immune foreigners living in screened quarters, only 6·6 per cent. were positive. Here it should be emphasized that these surveys were made on people performing their regular work—*not* bedridden.

A careful consideration of the above-named surveys enables us to draw certain conclusions.

Among the conditions that influence the incidence of malaria may be mentioned the following:—

First, rainfall. The greater the rainfall the greater are the opportunities for mosquitoes to breed, and the more anopheles mosquitoes there are the greater is the incidence of malaria.

Second, location of camps. In the camps located in good sanitary districts there is much less malaria than in those near swamps or other places where anopheles mosquitoes breed freely.

Third, screened quarters. The incidence of malaria among persons living in screened quarters is much lower than among those living in unscreened quarters.

Fourth, frontier camps. In such places, where the labourers are engaged in pioneer work, the incidence of malaria is much higher than in the older settlements.

Fifth, individual or racial immunity.

Sixth, impaired physical condition as a result of debilitating or complicating diseases.

The influence of rainfall is well exemplified in the Cuban Divisions, Banes and Preston, which are located near Nipe Bay, in the north-eastern part of Cuba. These divisions are approximately of the same size, have similar rainfalls, similar temperatures and similar classes of labour. They have entirely separate administrations. As can be noted from the temperature chart (page 185), the rainfall during 1923 in the Banes and Preston Divisions was 38·57 and 35·51 in. respectively. During that year the hospital admissions of patients with positive findings were 295 and 250 respectively, or 53 and 35 per 1,000 employees. In 1924, when the rainfall in the Banes and Preston Divisions was 59·41 and 60·49 respectively, the hospital admissions of patients with positive findings were 971 and 307 respectively, or 196 and 48 per 1,000 employees.

Clinical cases of malaria among the employees in Banes and Preston numbered 157 and 281 respectively. From this it is apparent that the additional rainfall markedly increased the number of employee hospital admissions. In the Preston Division the increase was much less marked than in the Banes Division, for the reason that in the Preston Division 15 gr. of quinine were given twice weekly to practically all the labourers, and this method was not followed in the Banes Division. The finding of a greater number of *clinical* cases in the *Preston* Division is due to the same cause; parasites are not readily discovered in the peripheral blood of those taking quinine.

The importance of other infections in lowering the resistance of the inhabitants in a malaria-infected district must be stressed. Dr. Clark, of the Tela Division, has shown that among 3,264 persons examined in 1923, the percentage of infestation by *uncinaria* was 40·1 per cent., by *Trichuris trichiura* 23·1 per cent., and by *ascaris* 19·5 per cent; and that of 3,240 examinations made in 1924, *uncinaria* infestation was found in 48·9 per cent., *Trichuris trichiura* in 28·5 per cent., and *ascaris* in 18·8 per cent. In addition to these infestations, *Oxyuris vermicularis*, *strongyloides* and *cestodes* were found in small percentages of the population of this division, and also *Balantidium coli* flagellates, and amœbiasis.

As regards amœbic infections, Dr. Clark examined the stools of only those patients suffering with some form of colitis, and the incidence of amœbiasis in the Tela Division is not properly represented by his figures. Drs. Kofoid, of California, and W. M. James, of Panama, have recently made a survey in the Colombia Division. Of 356 people examined by them, practically 50 per cent. were infected with *Amœba histolytica*. This survey was made among employees, and included persons apparently in good health, as well as some in the hospital under medical treatment for a variety of conditions. It is probable, therefore, that careful surveys of the other divisions would reveal a much larger percentage of amœbic infection than has been shown in our previous annual reports, for the reason that many obscure amœbic infections are discovered only by very careful microscopical examinations of the stools, with a view to finding this specific organism. A large number of cases with amœbic infection may not for years reveal symptoms that would lead clinicians to suspect its presence, inasmuch as many cases of amœbiasis do not suffer from dysenteric symptoms.

In addition to the infections referred to above, the Wassermann records, as shown in the following tables for 1923, 1924 and 1925, are also interesting:—

illiterate, so that it is very difficult to instruct them in sanitary matters.

Sixth, in most of the divisions the labouring population is extremely unstable; according to Dr. Clark, the turnover in the Honduras Divisions is as high as 50 per cent. per month.

WASSERMANN RECORDS, 1923.*

Race	Number tested	Positive (+ +)	Doubtful (+)	Combined percentage (probable syphilis)
Negroes and mulattoes	200	52 (26 per cent.)	18 (9 per cent.)	35
Latin-Americans	1,113	147 (13·2 per cent.)	75 (6 7 per cent.)	19·9
North Americans and Europeans	104	10 (9·6 per cent.)	13 (12·5 per cent.)	22·1
Syrians	14	2 (14·2 per cent.)	2 (14·2 per cent.)	28·4

Negroes	108	23	21·3
Foreign Whites	86	10	11·6
Chinese	2	0	0·0
Totals	1,913	287	15·0

* Based on number of individuals examined, and *not* the number of tests performed.

It will be noted in the above tables that the apparent incidence of syphilis was greater in 1923 than it was in the succeeding two years. This probably can be explained by the reason that prior to 1923 this condition was undiagnosed in many instances, as laboratory tests were not applied—and hence treatment was not instituted in all infected cases. With the aid of a laboratory diagnosis in 1923 and subsequently, it was made possible to treat *all known cases;* so that in the following two years (1924 and 1925) the percentage of positive Wassermanns may be considered as having reached a normal index in that community, which confirms also the results obtained in the Canal Zone and other large centres in this country.

Summarizing the above-mentioned conditions, we may make the following statements:—

First, judged from the standpoints of temperature and humidity, the conditions are favourable the whole year round for the multiplication of anopheles and for the sexual development of the parasite in the mosquitoes.

Second, the vast majority of the employees are labourers who live under primitive conditions, in unscreened houses. Among these persons, a large proportion of the population suffers from malaria infection. Many of them are gamete-carriers and, unprotected from the bites of mosquitoes, facilitate the spread of infection to others.

Third, many suffer from complicating infections and infestations that lower their normal resistance.

Fourth, malnutrition exists in a large proportion of these people because of insufficient or improperly-balanced diets.

Fifth, the great majority of the labourers are

Since conditions are as explained above, if any degree of malaria control is to be obtained the problems must be attacked from three angles:—

First, an attempt must be made to control the number of anopheles mosquitoes, and also to determine the species, since some of them are more important vectors than others.

Second, the malaria-carriers must be protected from anopheles contact.

Third, attempts must be made to cure the carriers.

In regard to the first of these measures, anopheles breeding places may be classified in two distinct groups. In one we have the natural breeding places, such as swampy localities, sluggish streams, ponds, seepage areas, &c. The second group consists of "man-made" breeding places—water tanks and smaller water containers of all kinds (some of which, like discarded cans and bottles, are useless and are left carelessly about); pits, ditches and similar excavations made during the process of building, road-making, and so on, and left open and neglected because some people fail to realize that these are potential breeding places for mosquitoes.

With respect to these two distinct groups of mosquito breeding places, we can expect to obtain in the first group only a very moderate control, unless unreasonable expenditures are made. Careful attention, however, should be given to the location of camp sites, in order that they may be established as far as possible from mosquito breeding places that cannot be economically controlled.

Another very important consideration is the trans-

mitting vector in any malaria district. Among the different species of anopheles that transmit malaria their powers of flight vary from one to two miles, and this fact should be taken into consideration in the selection of any camp site. All other conditions being equal, in the end it is far more economical to conduct water to a camp site or to dig wells than to locate the camp beside a body of water favourable for the breeding of mosquitoes. Of course, this is not always possible.

In any locality the sanitary measures necessary for the control of mosquitoes depend altogether upon the specific conditions. Many of these places can be controlled with reasonable expense, but many of them cannot; each must be the object of individual investigation.

As to the other group of mosquito breeding places, which we call the "*man-made variety*," there is little excuse for their existence. In many localities these are the most dangerous breeding sources because they are so often near the habitations. It is practically always possible in every community to limit the amount of anopheles breeding with only small expenditures, and thus lower the index in that locality; and the lower the index of mosquito breeding, the lower will be the malaria incidence.

Now, let us consider the second control-measure referred to; that is, the protection of malaria-carriers from anopheles contact. There is but one way to get this protection, and that is by means of effectively-screened houses. These, however, are of limited value unless the carriers remain behind the screens during the feeding hours of the mosquitoes—from sunset to sunrise. Many attempts have been made to screen the quarters of the labourers, but experience has taught us that screens cannot be maintained among the illiterate population, nor will the people seek the available protection during the time when mosquitoes are feeding. That screens are protective is amply demonstrated by Dr. Clark's recent survey in the Tela Division, where the percentage of infection among the non-immune whites living in screened quarters was only 6·6 per cent., as contrasted with the percentage of infection—29·1 per cent.—among the partially immune population living in unscreened houses. The survey of Garcia's plantation demonstrated the same thing—that effectively-screened houses are absolutely protective, but that they must be properly utilized. The right use of them necessitates a considerable amount of intelligence, education and willingness to obey sanitary regulations, and, unfortunately, these desiderata are not to be found in an illiterate population.

In regard to the third angle of approach—cure of the carriers—this is a phase of the malaria problem which has not been sufficiently stressed by malariologists. If our chronic cases could be cured or immunity could be developed, the various aspects of the malaria problem would be greatly simplified. It is patent to all experienced in the treatment of this disease that primary infections and acute exacerbations of chronic infections will yield rapidly to the administration of quinine, in the vast majority of cases; the chief difficulties consist in ridding of infection the chronic or relapsing cases. That immunity among individuals, and even races, does exist, or may be developed, partially or completely, is the belief of most malariologists. In every malaria-infected community there are some apparently immune individuals in whom malaria organisms cannot be demonstrated, and who for indefinite periods remain free from fever. Undoubtedly, in most of these instances, this immunity has been developed from attacks during childhood, though natural immunity seems to exist in a few individuals. In the surveys that have been made in Honduras, the percentage of infection is higher in children 10 years and under than in adults. This fact suggests that in children there is a low degree of immunity which probably increases as they grow older.

That immunity may become a racial development is shown by Pijper and Russell,[1] who refer to racial immunity existing among coloured races near Pretoria, South Africa. In the case of some of these people inoculation experiments completely failed to develop infection or else caused only such mild infections that cures occurred spontaneously This partial or complete immunity may explain why Pijper's and Russell's patients suffering from primary infections were so readily cured by arsenical injections. That immunity is the result of previous malarial infection, individual or racial, is a well-founded belief, and apparently demonstrates that man has defensive agents capable of being developed to protect him against the invasion of malaria parasites. The development of defensive agents is probably a function of the body cells or fluids so that these agents can function at their optimum only when the body is healthy and well-nourished.

Every experienced physician knows that a patient suffering from a disease has a better chance of recovery if there are no complicating infections or debilitating conditions. Furthermore, in every chronic condition the importance of nutrition cannot be overestimated. It is, therefore, easy to understand the difficulties experienced among our labouring population in the development of immunity, because of the numerous associated debilitating infestations and infections which exist. Our work must be directed not only toward mosquito control, but also toward the careful examination and treatment of our chronic carriers; and all associated or complicating conditions that tend to debilitate the patient must have due consideration and proper treatment. Some carriers, however, suffer from chronic, incurable, constitutional conditions or diseases that do not lend themselves to cure; hence these carriers remain a menace to the community in which they live. The only effective measure of protection for the community, therefore, lies in having the carriers live in effectively-screened houses. Continuous administration of

[1] A. Pijper, M.D., Consulting Pathologist to the Pretoria Mental Hospital, and E. D. Russell, M.R.C.S., L.R.C.P., D.P.H., Assistant Physician at the Pretoria Mental Hospital: "Observations on Inoculated Malaria." *South African Medical Record*, May 9th, 1925.

quinine will undoubtedly help to clear the trophozoites from the peripheral blood, but not always the gametes; and it is with these that we are chiefly concerned, as regards mosquito infection and the spread of malaria.

In communities where a large percentage of infection is prevalent, as determined by examination of the peripheral blood, it is astonishing to find what a small percentage of persons will be acutely ill and incapable of performing their daily duties. In the recent survey of several camps, made by Dr. Clark, of 2,742 people examined he discovered only one woman acutely ill, though 76 per cent. were positive and 81 of these had heavy infections. These patients apparently relapse or suffer acute symptoms only when they have been unduly exposed to rain or the direct rays of the sun, or when their power of resistance has been otherwise lowered temporarily, as, for example, by too much exertion. Rest in bed often is sufficient to re-establish the afebrile condition and enable the patients to continue their work. Many of the cases admitted to our hospitals are of this character. The temperature will fall after a preliminary dose of calomel, followed by Epsom salts, without even the administration of quinine, which, however, is always given routinely when malaria is suspected, whether parasites have been found or not. The administration of any sort of tonic drug to such patients would probably give similar results; we are often misled, attributing the improvement to the effect of a particular drug, when probably the same result would have been obtained even had no drug at all been given.

Patients who develop a partial immunity to malaria, and who have had an acute exacerbation readily become afebrile if their resistance is increased by any measure, no matter how simple or of what character.

In order that any satisfactory progress may be made toward ridding a community of malaria, an examination of all the inhabitants should be undertaken. The examination should not be limited to a testing of the blood for malaria infection, but should include also a thorough physical examination.

A certain percentage of the population will be found to have malaria infection and still be in apparently good physical condition; in fact, it is astonishing what a severe degree of infection may be found in certain individuals who are still able to perform their regular duties. Those in good physical condition can usually be treated at home, and administration of 10 gr. of quinine two or three times daily will rapidly clear the blood of parasites. Others, again, will be in poor physical condition. They may have light or heavy infections in the blood, associated with gametes. These are the cases which are largely responsible for the transmission of malaria and are perennial reservoirs from which mosquitoes become infected.

Thorough physical examination is necessary in order to determine the possible presence of other conditions, local or general, that lower the resistance of the patients, thus interfering with the possibility of getting rid of the malaria infection. Among the many complicating conditions may be mentioned focal infections, organic diseases, and acute or chronic infectious diseases, as well as different infestations.

According to our experience, when the patient's resistance is lowered by such conditions, it is impossible to get rid of a malaria infection by the administration of quinine only, no matter in what dosage it is given nor over what period of time. In other words, it is our belief that quinine takes care of malaria infections only when the patient is otherwise in good physical condition. Quinine does not kill parasites directly, but only in combination with some agent or agents in the body, and such an agent can act at its maximum only when the general physical condition of the patient is good.

Chronic cases, for the most part, demand care in a hospital, where thorough examinations can be undertaken and associated debilitating conditions treated, no matter what their character may be. In many cases long periods of treatment are necessary to rid the peripheral blood of gametes. Every gamete-carrier should be considered as a menace in a community, unless he lives in screened quarters, so that he is thus protected from the bites of anopheles mosquitoes.

In the treatment of acute malaria infections, whether primary or acute relapses, we have found no drug so effective as quinine or its salts in some form. But in the treatment of the chronic conditions, we have obtained much better results with a combination of drugs consisting of quinine, arsenic, iron and nux vomica. Therefore, we have devised for use on our plantations a tablet that contains quinine sulphate, 2 gr., reduced iron $\frac{3}{4}$ gr., arsenious acid $\frac{1}{50}$, and extract of nux vomica $\frac{1}{8}$. One or two tablets are given after each meal.

Because the defensive agents of the body which protect us from disease are many and elusive, probably both cellular and humoral, and because they are stimulated by many different drugs that have been usually considered as specific, it is not well to persist too long in the use of any single drug. If results are not obtained by use of one drug or one method of treatment within a satisfactory period, it is better to change to another agent. For example, we have found that in some chronic cases in which quinine, or combinations of quinine, iron and arsenic, fail to give results, iodides will effect the necessary stimulus; in other cases, alkalies; in still others, the newer arsenical preparations given intravenously, or the more recent therapeutic agents, such as stovarsol or mercurochrome. We are convinced, in other words, that proper treatment of a chronic malaria case, in order to bring about convalescence, not only taxes the diagnostic ability of the clinician, but also demands an extensive knowledge of the therapeutic action of drugs. In fact, in some cases it is necessary to resort to change of climate in order to give to the defensive agents of the body the stimulus necessary for them to throw off disease.

From time to time we hear of the apparently

specific action of a new drug in the treatment of malaria. It is quite possible that certain cases would yield to the effect of some new preparation, or some old preparation, if we were only able to determine and select the proper agent to use. We are under the impression that in many of these chronic cases large doses of quinine should not be continued for more than ten days, or fourteen days at most; that they then lose their specific usefulness and probably depress the patient. After this period, better results are obtained from the tonic doses of quinine in combination with other drugs.

The remarks made above can probably be best illustrated by means of the following case reports:—

Case I.—This was a case of persistent tertian malaria in an educated white man who has lived in the coast climate of Guatemala for eighteen years.

He had suffered a great deal from malaria, and at intervals had taken large amounts of quinine and arsenic. His recent history is as follows:—

In July, 1923, he became quite ill with malaria —mixed infection—and was given a course of quinine. He took 45 gr. daily for ten days, and 30 gr. daily for six weeks subsequently. During the latter part of this period he was in Europe. While there he stopped taking quinine for about a month and then had another malaria attack, with two definite chills on alternating days, after which he resumed his quinine. He continued to take 30 gr. daily until about the middle of January, 1924. Meanwhile, in November, he had returned to the tropics, where he lives under excellent sanitary conditions and is very little exposed to re-infection, as he lives in a screened house.

During the early part of March, his tertian malaria symptoms returned. For two weeks he took 45 gr. daily, then 30 gr. daily for eight subsequent weeks, and 10 gr. daily for several weeks after that. While still taking 10 gr. daily, he fell ill with malaria about July 12, 1924, and went back to 45 gr. a day for three weeks, subsequently continuing to take 30 gr. of quinine daily. This treatment he kept up for three months, when he reduced the dosage to 20 gr. daily, which he continued until February 1, 1925.

About this time he felt very achey in the limbs, and suffered from lassitude and other "malaria-like" symptoms. A thick-film smear showed pigment and one tertian gamete. After a consultation with several physicians, he was advised to take 30 gr. of quinine daily, 5 min. of Fowler's solution three times daily, and ½ oz. of Warburg's tincture with aloes three times daily. He adopted this treatment, and kept it up for fully five weeks; then he discontinued the Fowler's solution and took a weekly injection of salvarsan instead. In addition to this, twice a week he took intramuscular injections of 15 gr. of quinine, replacing the former evening doses by mouth.

On Monday, April 13, he was playing golf in the sun when he had a moderate chill, and went to bed with a temperature of 103° F. He complained of pain in the spleen, which, on examination, was found to be slightly enlarged. His trouble proved to be a typical tertian paroxysm. The next afternoon his temperature rose to 100·5° F., then dropped and the following day rose to 100° F. With this recurrence on Monday, April 13, all previous treatment was discontinued. A purge was given and he began the use of stovarsol, taking four tablets during the first twenty-four hours, and three daily thereafter until twenty-five had been taken.

Two weeks later the patient reported that he felt better than he had "in many moons." His tongue, which had been filthy for over a year, was almost clean, his appetite was better than it had been for months, and the tired feeling in his legs and shoulders had practically disappeared.

On October 9, 1925, the patient reported at my office, after a prolonged vacation in Europe, and stated that he was now feeling better than he had felt in a great many years.

The brilliant results obtained in this case from the use of stovarsol determined us to give it a trial in some acute cases. In this connection, two brief case reports on young men, 18 years of age, may prove of interest.

They were admitted to the Tela Hospital in Honduras on May 4, 1925, and were discharged at their own request on May 25. On admission, the one had a massive infection of E.A. malaria, and the other a massive infection of tertian malaria. In the latter case, E.A. parasites were also discovered in his peripheral blood a few days after admission. Both of these men had infections, too, of *Amœba histolytica*, accompanied by dysentery. Apart from the usual clinical manifestations of malaria, there were no other physical positive findings. The Wassermann reactions in both cases were negative.

Both of these patients were given a course of emetine, and each received a tablet of stovarsol three times daily. From the date of their admission until the date of their discharge, their bloods were examined daily by Dr. H. C. Clark, using the "thick-film" method recommended by Barber. After three days' treatment, the parasites in the peripheral blood were found to be increasing in numbers, with a corresponding increase in the gravity of the symptoms. The administration of quinine was immediately resorted to, and in one case hypodermic injections were found necessary in order to save life. Each patient received 40 gr. of quinine daily, by mouth, during the subsequent hospital period, the one taking 680 gr. in all by mouth, and the other 640 gr. plus 45 gr. by hypodermic. The daily examinations of the peripheral blood by Dr. Clark revealed crescents in the majority of the fields examined during the entire hospital period. For the last few days of their stay in the hospital, notwithstanding the presence of crescents in the peripheral blood, they had been up and about, feeling perfectly well. They themselves requested their discharge from the hospital.

It will be noted that stovarsol was of no value,

apparently, in controlling the development of malaria parasites. It was necessary to resort to quinine in order to save the lives of the patients; and notwithstanding the large amount of quinine taken by these patients, crescents were still present in their blood when they were discharged. Since these cases were reported, similar results have been obtained in a great many other instances. As demonstrated in the first case reported, however, stovarsol in some chronic cases will prove of undoubted value.

In reviewing the conditions with which we have to contend on our plantations, if we are effectively to control malaria, we would submit the following recommendations:—

First. There should be reasonable mosquito control for a radius of from one to two miles from the settlements. This, of course, necessitates use of sanitary measures in the immediate vicinity of the dwellings, as well as control of anopheles breeding in all water containers and ponds throughout this area. Such control can be economically accomplished by means of drainage, filling, fish-stocking, or else by larvaciding with Paris green or petroleum products.

Second. In new plantation work, where the conditions can be anticipated, careful selection of camp sites is always of great importance. Too often these locations are selected because of proximity to supplies of water, where mosquito breeding is perennial. If a camp site can be established one or two miles from a mosquito breeding source, it is much more economical in the long run to convey water there or dig wells, than it is to endeavour to protect the population from mosquitoes.

Third. An endeavour should be made to stabilize the population. A stable population can be gradually educated in the simpler methods of sanitation and, eventually, real co-operation can be obtained. Where there is a labour turnover of 25 per cent. every three or four weeks, the difficulties of maintaining sanitation are much greater. In order to stabilize the labouring population, we must not only build and maintain attractive and comfortable camps, but we must also provide measures for taking care of the families of married men, by furnishing them with garden facilities, schools and some forms of entertainment. In other words, we must take an interest in our people if we may hope to retain their services indefinitely. In the schools the principles of sanitation should be taught, the children should know how malaria, hookworm and other infections are contracted, and how they can be avoided. Thus, in the course of a few years, all inhabitants of the region would have a certain amount of knowledge of what measures are necessary if they are to protect themselves.

Fourth. Now the next important step can be taken—namely the screening of houses. With an ignorant population, it has been demonstrated time and again that the screens generally cannot be maintained, and even if they can be, they are of very little use to the people unless the latter are educated to appreciate the value of screens, and to realize that everyone must use the protection afforded, during the hours when anopheles are seeking warm blood. On the plantations, no public gatherings in the open at night should be permitted, but a screened meeting-house should be used. It could serve as a school in the day time, and at night for entertainment. All offices where work is necessary after sundown should be screened. In those few instances in which men are compelled to work in the open at night, prophylactic quinine should be given as a preventive. Probably fifteen grains of this twice a week will keep the peripheral blood sufficiently free from parasites to prevent mosquito infection.

General adoption of these measures not only would control multiplication of mosquitoes, and thus lower the index, but at the same time would protect the inhabitants who are already infected, and thus prevent spread of the disease.

Another measure to be aimed at is to attempt to *cure the carriers.* Careful physical examinations must be made, in order to discover complicating conditions that lower the resistance of the patient and prevent the natural defensive agents of the body from throwing off the malarial infection. All complicating conditions must be treated as well as the malarial infection—a requirement which will try the diagnostic ability and therapeutic resourcefulness of the physician.

There is no agent which, in primary infections or acute relapses, will give the same results as salts of quinine; but after the acute symptoms subside, then we must try to build up the system by all the means at our disposal, and in some instances we must resort to a change of climate in order to accomplish our purpose.

The chief difficulties in curing malaria cases are connected not with the acute forms of the disease, but with the chronic relapsing cases which carry gametes in the peripheral blood, and through which the disease spreads and is perpetrated.

Since writing the above, my attention has been directed to a report by Dr. Nocht on the work of the malaria commission of the League of Nations in the fight against malaria. The review of this publication in the *Journal of the American Medical Association* dated January 23, states as follows:—

"The only European region that has actually been freed of malaria is a certain part of Dalmatia. Water is scarce and is collected in deep, protected cisterns. The scanty shallow pools were sprayed with oil. The entire region has thus been freed of mosquitoes and malaria. Conditions have also been favourable for extermination of malaria in Palestine, he adds. There is no rainfall during the malaria season, and extensive regions have been cleared of mosquitoes. The malaria commission concluded its work by advising to limit the campaign against mosquitoes to certain regions where conditions favour it. Planless spraying with oil, draining, breeding of fishes, are only throwing money away. A single overlooked breeding-place may infect a whole village. The main reliance

must be on thorough treatment and after-treatment of every case of malaria, and discovery and treatment of every one infected with malaria (house-to-house visitation, examination of school children, &c.) and education of the public to seek out and destroy the mosquitoes that lurk in the bedrooms and living rooms, and to protect against mosquitoes by nets and screens and white walls. Quinine as a prophylactic is advised only in exceptional cases and with the strictest surveillance."

It is interesting to note that the conclusions of the malaria commission of the League of Nations are substantially the same as those expressed in this article.

FURTHER EXPERIMENTS WITH THE *GONGYLONEMA* OF CATTLE.

By H. A. Baylis, M.A., D.Sc., A. Leslie Sheather, D.Sc., M.R.C.V.S., and W. H. Andrews, D.Sc., M.R.C.V.S.

The question of the distinctness of certain forms of *Gongylonema* in domestic animals is a difficult one. Morphological studies have led one of us (Baylis, 1925, *a*, *b*, *c*), to maintain the view that it is impossible to recognize specific differences between *Gongylonema pulchrum* Molin from the pig and wild boar, *G. scutatum* (Müller) from ruminants, *G. ransomi* Chapin from the pig in America, and *G. subtile* Alessandrini from man. All these, and several other imperfectly-known forms, have been regarded as a single morphologically variable species, for which the name *G. pulchrum* Molin, 1857, has been used.

Experimental evidence appeared to be necessary if any further light were to be thrown upon the question. If it could be clearly shown that a form of *Gongylonema* parasitic in one host could be experimentally transmitted to another host, there might then, it was thought, be reasonable ground for concluding that the morphologically similar forms naturally occurring in these two hosts were identical. It should be borne in mind, however, that a negative result obtained by this method cannot, of itself, definitely decide the question of species. At the most it can only provide information which suggests that some physiological difference exists between one set of individual parasites and another. Whether that physiological difference is the expression of a specific, varietal or racial distinction of some kind, and if so of what kind, will still remain a matter of opinion.

The experiments recorded in this paper were undertaken with a view to determining, if possible, the extent to which the *Gongylonema "scutatum"* of cattle can be transmitted to other hosts. The infective material used consisted of (*a*) specimens of the small cockroach, *Blattella germanica*, which had been experimentally infected with the larvæ of the bovine *Gongylonema* in Italy (see Baylis, Pan and Sambon, 1925), and (*b*) specimens of various dung-beetles obtained from cow-dung at the village of Villa Lagarina, in the Trentino, Northern Italy. A certain percentage of these beetles was known to be fairly regularly infected with the larvæ of *Gongylonema* (see the paper referred to).

For the purposes of the experiments healthy young English animals were used, which were extremely unlikely to have come in contact with *Gongylonema*. *G. "scutatum,"* in fact, appears to be extremely rare or possibly absent altogether in this country. A calf about six months old, three two-year-old sheep and three pigs about three months old were obtained, and throughout the experiments were kept confined in stables at the Research Institute of the Royal Veterinary College. The experiments were carried out in continuation of investigations begun in Italy with the aid of a grant from the British Empire Cancer Campaign.

Calf.—On October 5, 1925, the calf received four specimens of *Blattella* from a batch experimentally infected with *Gongylonema* larvæ. The insects were broken up and placed in water, which was then administered to the animal as a drench. When killed on February 25, 1926 (*i.e.*, about twenty weeks from the date of the infective feeding), the animal was found to be heavily infected with adult *Gongylonema*, the lining of its œsophagus containing not less than eighty of the worms.

Sheep No. 1.—On October 5 this sheep received, like the calf, four of the infected *Blattella*, administered in the same way. When killed on February 25, it was found to be somewhat heavily infected with adult *Gongylonema*, at least forty-six individuals being present in the œsophagus.

Sheep No. 2.—This animal received on October 5 about twenty dung-beetles, broken up and given as a drench with water. At least three species of beetles were included in the dose (*Onthophagus taurus*, *Caccobius schreberi*, *Sphæridium* sp.). On November 11 a larger dose of beetles was given (about seventy), of which, this time,[1] about thirty were *Aphodius fimetarius*, the remainder various other species of *Aphodius* (not definitely known to act as hosts of *Gongylonema*), and a few *Sphæridium*. On November 14 another dose of about ninety-five beetles was given, of the same kinds as on the previous occasion. When killed (on the same date as the preceding animals, February 25), this sheep was found to have fifteen adult *Gongylonema* in its œsophagus.

Sheep No. 3 was kept as a control, and lived in the same stable and under the same conditions as the other two sheep, except that it was not fed with cockroaches or beetles. It was killed on March 5, and showed no infection with *Gongylonema*.

Pig No. 1 was treated similarly to the calf and sheep No. 1, i.e., on October 5 it had five *Blattella* administered to it in water as a drench. When killed on February 25 it was found to be entirely free from *Gongylonema*.

Pig No. 2 received exactly the same treatment as sheep No. 2, being fed on October 5, November 11

[1] The beetles used for the first dose were the survivors of a stock brought to England early in September, and the species represented were those most abundant during the summer months. The beetles used for the subsequent doses were received later from Villa Lagarina, and consisted of autumnal species.

and November 14 with dung-beetles. On the first occasion it received about twenty beetles, on the second about seventy, and on the third about ninety-five. The beetles were of the same kinds, in about the same proportions, as those received on the several dates by the sheep. The first dose was administered in water, but on the other two occasions the living beetles were mixed with the animal's food (mash), and were readily devoured. The pig was killed on February 25, and was entirely negative for *Gongylonema*.

The third pig was kept as a control, but as the two that had been experimentally fed were negative it was not thought necessary to destroy it.

During the period of twenty weeks occupied by the experiments the fæces of some of the animals were examined at intervals by the sugar flotation method[1] with a view to ascertaining, if possible, whether infection had taken place. In the cases of the calf and sheep it was a simple matter to obtain a small sample of fæces direct from the rectum, but this was not readily done in the case of the pigs. After the first few days, therefore, the pigs were penned separately and the fæces for examination were collected from the floor. In all cases the amount of fæcal matter taken was approximately the same and was about equivalent in volume to a hen's egg.

The fæces of the calf, sheep No. 1 and pig No. 1 were examined more frequently than those of the other animals because it was known that the cockroaches with which they were fed had been infected experimentally with *Gongylonema* larvæ, whereas it was not known whether the individual dung-beetles used were infected or not. The fæces of the calf and sheep No. 1 were examined on twenty-six occasions, and those of pig No. 1 on sixteen. Thirteen examinations were made of the fæces of sheep No. 2 and eight of those of pig No. 2. On some occasions special attempts were made to concentrate any eggs that might be present, by repeatedly adding fresh material to the same fluid and centrifuging again. In no instance were the eggs of *Gongylonema* detected.

It was thought possible that the eggs of this parasite might sink in the sugar solution used instead of rising, and to test this possibility the sediment obtained in the tubes was subjected to scrutiny on some half dozen occasions, but in all cases the result was negative. It is perhaps worthy of mention in this connection that although the fæces of the sheep constantly contained eggs of nematodes other than *Gongylonema*, yet, after flotation, none were found in the sediment when this was examined.

It has to be admitted that, in view of the facts recorded, examination of the fæces by the method employed is not a suitable means of detecting *Gongylonema* infections during life, but when it is considered how small was the sample examined, compared with the amount of fæcal matter passed each day, it is perhaps not surprising that the eggs, if they are swallowed and passed out with the fæces, escaped detection.

[1] Sheather, *Journ. Comp. Path. & Therap.*, 1923, June, vol. 36, No. 2, pp. 71-90.

The possibility that eggs might tend to pass up the œsophagus, and escape by the mouth, was also considered. On two occasions direct examination was made of the material (chiefly saliva) obtained from the calf and sheep by gently scraping the tongue and the mucous membrane of the cheeks. The second examination was made on the day preceding the slaughter of the animals, but in no case were eggs detected.

Discussion of Results.

These experiments appear to indicate that :—

(1) There is no difficulty in transmitting the *Gongylonema "scutatum"* of cattle to sheep.

(2) It is difficult or impossible to transmit the *Gongylonema "scutatum"* of cattle to pigs.

With regard to the first of these conclusions it may be noted that the question of a specific distinction between the *Gongylonema* of cattle and those naturally occurring in sheep and other ruminants seems never to have been raised. It has always been tacitly assumed that "*G. scutatum*" is the same species, whether it occurs in cattle, buffalo, sheep, goat or any other ruminant. The bovine form of *Gongylonema* has already been successfully transmitted to a sheep by Ransom and Hall (1915) by feeding the animal with experimentally-infected *Blattella*. The positive results of this and our own similar experiments are in accordance with the belief that a single species is involved.

With regard to the second conclusion, an experiment is recorded by Ransom and Hall (1915) in which a pig, fed on *Blattella* experimentally infected with the cattle *Gongylonema*, gave a negative result. The pig was killed two months after the first of two experimental feedings. It is doubtful whether this is a long enough period for the development of the worms to maturity, but had any worms been present they would probably have been sufficiently well grown to be easily detected. Our own two pigs were given a considerably longer time, and had, presumably, as good a chance of infection as the other animals fed on the same material. Ransom and Hall state that the negative result of their experiment with the pig is "suggestive of a specific infectivity and strengthens the idea that the hog nematode is a distinct species." Our own results were similar, but we cannot agree, as has been pointed out above, that this necessarily gives any ground for regarding the parasites as *specifically* distinct. It is quite possible that after a number of generations certain strains of the same species may become peculiarly adapted to certain particular host-species, and may lose to a greater or lesser degree their power of adapting themselves to another host. These strains may be on the way to the formation of distinct species, and may be regarded as "incipient" species, but in the absence of recognizable morphological differences this cannot be laid down as an established fact.

In connection with the result of the experiments on pigs, it is of interest to recall the result of an earlier experiment on rats, which has already been placed on record (Baylis, Pan and Sambon, 1925).

In this experiment two rats were successfully, though slightly, infected with the *Gongylonema* of cattle. It is somewhat surprising, in view of this, that the pigs remained negative, for it might have been expected that the conditions afforded by the pig would be more suitable for a parasite of other ungulates than those afforded by a rodent.

AN EPIDEMIC OF CHOLERA AMONGST BALLAST TRAIN COOLIES IN BENGAL.

By E. N. D. REPPER, M.B., Ch.B.

THE successful treatment of cholera in its epidemic form is never an easy matter, but when the outbreak occurs among coolies on a ballast train the difficulties are greatly enhanced, due to the conditions under which these people live.

To those not conversant with railway workings I will give a short account of the type of ballast train in use on the Indian railways.

The train consists of about 35 to 40 open trucks, such as are used for carrying coal, &c., and is under the charge of a European or Anglo-Indian guard. These trains move from point to point on the line carrying ballast, bricks, sleepers, &c., and are loaded and unloaded by the coolies. Each train carries 160 to 180 male and female coolies besides children, of whom there are usually many. These coolies are mostly Sonthals, one of the primitive tribes, a very suspicious and illiterate people, who at times are very difficult to manage. They make their home on the train by covering one-half of their wagon with a tarpaulin. Here they live with their wives and families. Many of them are born on the train and live there all their lives.

In March this year, three trains working on my section, carrying over 500 coolies, were practically simultaneously attacked with cholera, so it was decided that the only way to deal with this outbreak successfully was to find a suitable place for a cholera camp, have the trains brought there, segregate the whole of the coolies, to prevent their absconding, which they always do if possible, being so afraid of cholera, and thereby prevent the epidemic becoming widespread.

Having decided to form such a camp, there are several points which have to be considered with regard to the choosing of the site.

(1) It is absolutely impossible to allow the infected trains to remain on the main line, so a siding has to be chosen, which must be large enough to accommodate all and also to allow for segregation of the infected wagons from the non-infected. Failing this a piece of ground large enough to encamp the coolies with a zone of safety between the infected and the non-infected tents.

(2) A good and plentiful water supply is an advantage, but if not available the difficulty can be overcome by making the coolies draw their water from the engines of their respective trains, provided that there is a watering station within reasonable distance of the camp, where the engines can replenish their supply.

(3) The site chosen must be in a sparsely populated area. If put near a town or village the inhabitants will immediately raise a hue and cry. In this respect an unimportant branch line is the most suitable situation.

(4) Food must be available for the coolies.

In choosing the site for our camp we were fortunate, inasmuch as we were able to utilize a large stores siding on one of the branch lines, which conformed with the above. The ground was rather low-lying, but the whole of this part of Bengal is much the same. In fact, some parts of it are below sea-level. The siding was situated some 20 miles from the place where the coolie trains were working.

Immediately the site was chosen orders were given for the trains to proceed there at once, for cholera huts to be constructed, for latrines to be dug and for the water supply to be guarded to prevent pollution by the infected coolies.

Two of the trains got to the camp without any trouble, but the coolies from the third train got down at one of the stations and refused to go back to the train. After a good deal of persuasion, they again boarded the train and it proceeded to its destination without any further hitch.

As each train arrived at the camp the infected wagons were uncoupled and shunted into one siding and the non-infected were put into another.

The whole of the camp was surrounded by a cordon of police to prevent the coolies from absconding. A certain number of them did manage to get away, but the number was negligible.

PROPHYLAXIS AND TREATMENT.

The coolies had to a certain extent been treated while the trains were on the line, but this was augmented as soon as they arrived at the camp.

NON-INFECTED.

Every non-infected coolie was given 1 oz. of the following mixture twice daily:—

℞	Acid Sulph. dil.	...	15 m.
	Tr. Opii ...	...	10 m.
	Aq. Chlorof. ad	...	1 oz.

The issuing of this medicine was a very fatiguing job, as every man, woman and child made it his business to be as stubborn about taking the medi-

cine as possible. The difficulty of the situation was also increased owing to the fact that these people speak a very different language from the ordinary Hindustani, and only one man among us could converse with them. However, after a great deal of trouble we managed to convince them that the medicine would make them less liable to be attacked with cholera, and then they took it without any trouble.

These coolies were made to take the tarpaulins off their wagons and use them to make tents. The tarpaulin was supported by three pieces of bamboo, two upright and one across and pegged to the ground at the edges. In this way a sort of large-sized bivouac was formed for each coolie and his family, the ground inside being covered by another tarpaulin. Here I may say that luck was with us, as if it had rained we would have been in a predicament, as the tents were by no means weatherproof.

The wagons were then thoroughly disinfected with izal and then exposed to the sun to complete the disinfection.

We had one accident with the tents. A coolie and his family were sleeping in a tent with a brazier burning inside and in the morning we found six of them suffering from CO poisoning. However, they recovered and were none the worse for it.

Arrangements had to be made for feeding these coolies, so we fixed what we considered to be a fair ration for a man, a woman and a child, and having calculated the quantity of food required for each train we issued this to the headmen, who in turn distributed the food to the coolies. Rice, dhal, oil, potatoes, spices and tobacco or cigarettes were distributed among them every day. The quantity supplied was more than sufficient, they being better fed than they had ever been in their lives before, but they were not satisfied, as the rations did not include native liquor, of which they are very fond.

Infected.

These gave us far more trouble than the others. They refused to go into the cholera huts which had been erected for them, as these huts were supposed to harbour ghosts. We tried to persuade them to do so, but they still refused; so, seeing that they were adamant, we decided to leave them in their wagons and treat them there. Here they were treated in as good a manner as could be expected under these conditions.

They gave a certain amount of trouble over the taking of their medicine, but when we attempted to give them saline they made a terrible fuss. Intravenous saline was attempted, but it had to be abandoned, as the patients and their relatives created so much disturbance. The Sonthals are very much against operative treatment in any form. We then tried subcutaneous saline. It was only by holding the patient and getting it in as quickly as possible that this was managed, but we succeeded in the majority of cases. A dirty ballast wagon is not an ideal situation in which to undertake the giving of saline, but in this case there was no other alternative. A certain number refused all treatment, and all the deaths which occurred in the camp, except one, belonged to this category. Every patient to whom saline was given recovered, and many of these were in a very bad state when treated.

As regards feeding, they were all given plain barley water during the acute stage and milk diet was available for them afterwards, but immediately they got over the acute stage they ate their ordinary food. It was useless to try to prevent their doing so. We tried but we failed.

Results.

Taking into account the difficulties with which we had to contend, the results were, on the whole, highly satisfactory. There were in all 40 cases, of whom 17 died.

They were divided among the trains as follows:—

	Complement	Cases	Deaths	Cured
Train No. 1 ...	167 coolies ...	16 ...	11 ...	5
,, 2 ...	187 ,, ...	11 ...	5 ...	6
,, 3 ...	175 ,, ...	13 ...	1 ...	12
Total ..	529 ,, ...	40 ...	17 ...	23

Of the above, 34 cases occurred before the trains were sent to the camp, and 12 of them had died before the trains arrived there.

	Cases	Deaths
Train No. 1 ...	13 ...	7
,, 2 ...	9 ...	4
,, 3 ...	12 ...	1
Total ...	34 ...	12

There were 22 cases on the trains when they arrived at the camp. Most of these were given treatment, but a few refused it and 3 of these died. One of the number who were treated also died.

The first day after arrival in camp there were 3 fresh cases, no deaths.

The second day there were 3 fresh cases, 1 death.

The third, fourth, fifth and sixth days there were no fresh cases, and so on the seventh morning the non-infected coolies were allowed to go to their homes, after each coolie had thoroughly washed his clothes in water to which a disinfectant had been added.

The convalescents were kept until they were fit to travel. This took until the morning of the tenth day, when they were also sent to their homes.

The figures in this outbreak show that the only method of treatment under conditions such as these is immediate segregation. Train No. 1, which was the longest time after infection in reaching the camp, shows the most deaths (11). Train No. 3, which was the shortest time after infection in reaching the camp, shows the least (1).

The whole epidemic subsided 48 hours after the trains were segregated in the camp.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All literary communications should be addressed to the Editors.

4.—All business communications and payments, either of subscriptions or advertisements, should be sent to the Publishers of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is Thirty Shillings per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—Special Notice.—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to 25 reprints, free of charge.

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

Tropical Medicine and Hygiene

JULY 1, 1926.

THE DIAGNOSIS OF TROPICAL FEVERS.

THE accurate diagnosis of a tropical fever may be a comparatively simple matter, or it may, on the other hand, present almost insuperable difficulties, taxing the diagnostic acumen of even the most experienced practitioner to the utmost, even when supported by every aid that specialized methods of examination can provide.

In the first place, a complete and systematic clinical examination of every febrile patient is most essential, and he should be most carefully examined in every organ and every part of the body, from the crown of the head to the soles of the feet. It is the sum total of the various symptoms, none of which are alone pathognomonic, on which the diagnosis is established, and, along with the symptomatology, support for the diagnosis may also be sought from the results of laboratory investigations, the application of X-rays, and other special methods. The importance of clinical methods, however, cannot be overestimated, and it has even been suggested that a practitioner who is unable to form a diagnosis in such cases without the assistance afforded by the results of laboratory investigations should utilize his earliest spare moments in pursuing a course of post-graduate instruction in clinical methods. At the same time laboratory work should never be omitted as a check to confirm or to adjust the clinical diagnosis. It is essential also that the material submitted for examination in the laboratory should be properly collected with all the requisite precautions and should be transmitted to the laboratory without delay.

The collection of this material should always be made, or at least supervised, by the practitioner; it should not be left entirely to subordinates, otherwise unsuitable material may be sent and misleading reports returned. Clear and definite instructions should also be sent as to the nature of the examination required, together with a brief statement of the salient features of the case and the suspected clinical diagnosis.

It must, of course, always be ascertained that the thermometer reading on which the recognition of the febrile condition is based is an accurate index of the body temperature of the patient, and the various thermometrical fallacies have been considered and ruled out. Thus the fact that hot or cold substances have recently been placed in the mouth may give rise to fallacious readings. Again, when working in high air temperatures, the clinical thermometer, being of the maximum type, will rapidly rise to the temperature of the external air and remain thereat. Under such conditions the thermometer should be taken out of cold water and then placed in the patient's mouth, where it should remain sufficiently long to be raised to the actual temperature; it should then be quickly replaced in the cold water, in which it is examined and the reading taken.

The fevers encountered in the tropics may be classified, according to their duration, into acute and chronic, and the acute fevers may, for diagnostic purposes, be divided into those which have been in progress less than eight days and those which have lasted eight days or more when seen by the practitioner.

Acute fevers of less than eight days' duration

may or may not exhibit some striking physical sign. The physical signs to be considered include traumatisms, skin eruptions—whether erythematous, papular, urticarial, purpuric, vesicular, bulbous, pustular, or pigmented; derangement of some bodily system—whether elementary, respiratory, circulatory, urinary, generative, lymphatic, muscular, osseous connective tissue, or nervous; and those in which the signs and symptoms are associated with some organ of the body, and the condition and functions of the following organs should be carefully investigated in this connection, namely, spleen, liver, kidneys, pancreas, parotid and suprarenal capsules.

Fevers of more than eight days and less than six weeks' duration may be classified according to the type of fever present, whether intermittent, remittent, or continuous, and whether marked physical signs are present or absent.

The various laboratory investigations that may be undertaken to help in the elucidation of this condition call for the resources of a well-equipped laboratory. Microscopic examination of well-made blood films and of fæces, sputum, and other secretions, blood- and stool-cultures, serological examinations, including the methods of agglutination, complement-fixation, and bacteriolysis, microscopic, bacteriological and chemical examination of the cerebro-spinal fluid, and many other biochemical investigations may be called upon to furnish results. X-ray examinations may also be used to throw light on the condition of the various organs, especially those within the chest. Lastly, the therapeutic test may be made use of.

A fever of syphilitic origin yielding to the administration of mercury and iodides, one due to malaria to quinine, &c., whilst atropine has been employed in the differentiation of fevers belonging to the enteric group. F. E. T.

Salmon in a diet for the Prophylaxis of Goitre (N. D. Jarvis, R. W. Clough and E. D. Clark, *Journal of the American Medical Association*, May 1, 1926).—In a group of susceptible persons just as great or greater immunity was produced with three as with five injections of scarlet toxin. The dosage suggested by the findings is 500, 5,000 and 30,000 skin test doses respectively, with an interval of two weeks between injections. This method of immunization is now in routine use in Michigan state institutions. The time interval of two weeks is considered important as there seems to be less systemic reaction and greater immunity produced than with the usual one week interval. Clinical and laboratory findings showed no injurious effects on the subject following the relatively large dose of toxin used in the third injection. This investigation is being continued on a larger scale.

Current Literature.

INDIAN MEDICAL GAZETTE,

March, 1926.

Differential Diagnosis in the Tropics (A. H. Proctor).—This paper is written in the hope of helping practitioners in the tropics where diseases, which in other countries are straightforward, are nearly always complicated, and therefore difficult to diagnose. Malaria, one of the commonest of tropical diseases, is very often associated with dysentery, cholera, respiratory conditions and many others. Of 426 cases admitted to hospital for various affections, the diagnosis of malaria was only arrived at after a stay in hospital. In cases of vomiting, the blood should always be examined for malaria parasites, or examination of the spleen should be made. Kala-azar is the next on the list with frequent complications, and is very often erroneously diagnosed as enteric fever. Points of value in the differentiation of these two diseases are, firstly, the spleen steadily enlarges with the duration of the fever in kala-azar and as a rule it reaches a larger size than it does in enteric. Secondly, the general condition of the patient is, as a rule, less toxic than the duration of the fever would lead one to suspect. Thirdly, there is progressive leucopenia, so that the proportion of white cells to red cells falls below 1 in 1,000. Fourthly the double rise in twenty-four hours. Malignant endocarditis is also commonly mistaken for kala-azar. Affections by *Entamœba histolytica* are commonly associated with diarrhœa and constipation and other affections, and in these cases a thorough examination of the stool is necessary. It should also be borne in mind that many tropical diseases present themselves in atypical forms which mimic other diseases. Other diseases, such as ankylostomiasis, leprosy, schistosomiasis, &c., will be discussed at a later date.

The Treatment of Lacerated Wounds within Two Hours (R. J. L. Sladen).—This method is ideal from an economical point of view; it is used in all the hospitals of the G.I.P. Railway, and the railway staff, amongst whom lacerated wounds are of frequent occurrence, are enabled to return to their duties after a very short absence from work. The treatment is carried out on the following lines: (1) To stop all hæmorrhage. (2) Place a sterile swab over the wound. (3) After thoroughly washing the hands with hot water, soap and a nail-brush wash the surrounding skin for at least 18 in. around the wound with the same. (4) Wash the wound in every crevice with hot water and soap. Nos. 3 and 4 may be left out unless the wound is very dirty. (5) Cut away loose tags of muscles and skin with sterilized scissors and forceps. (6) Wash every crevice with spirit applied with a sterilized swab. Paste every portion of the wound with B.I.P.P. (liquid paraffin 1 oz., bismuth subnitrate 1 oz., iodoform 2 oz.) applied with a sterile swab, taking care to leave very little in the depth of the wound. (8) Sew up the wound. Apply tincture of iodine and dress with dry steri-

lized gauze or lint. (9) An anæsthetic is nearly always necessary. (10) There is frequently a rise of temperature which does not necessarily indicate that the wound is not doing well. (11) The dressings may be left on up to a week if there is no local pain, but should be otherwise removed sooner. There is no harm in daily dressing provided the wound is kept dry and sterilized dressings applied. When redressing, keep the wound dry, use Friar's balsam, tincture of iodine or methylated spirit. (12) Iodoform poisoning may possibly occur, but has been most unusual.

Bombay Millponds and Anopheline Control (P. A. Dalal).—From this study it would appear that Paris green affords an ideal adjunct to anti-anopheline work. In the cases of large sheets of impounded water, as ponds and tanks and large swamps, where the use of oil or other larvicide would be enormously expensive and therefore impracticable, Paris green would appear to be a most valuable remedy to adopt. It is stated that domestic animals come to no harm by drinking the water of ponds treated with Paris green and that fish also are not killed by its use.

On the Inefficiency of "Mercurochrome 220" in the Treatment of Malaria (J. D. Dundas and D. M. Telang).—Treatment of six cases of malaria with "Mercurochrome 220" has given very unsatisfactory results. It had no effect on the malaria parasites even after two doses, and stomatitis and ptyalism were marked features in every case. The drug appears to irritate the kidney tissue to the extent of producing mild nephritis. It certainly cannot be claimed as an equal to quinine in the treatment of malaria.

Indian Digitalis (R. N. Chopra and Premankur De).—Digitalis is used in large quantities in India by the medical profession, but most of it is imported, and it was with a view to seeing whether preparations could be made from the Indian leaf that these investigations were carried out. The imported digitalis preparations are liable to lose 20 to 40 per cent. of their potency in a short time, besides being an economic problem. The digitalis leaf of good quality grows on the valley of Kashmir, Northern Himalayas, and at Mungpoo, Eastern Himalayas. The leaf grown in the Nilgiri Hills is not so good when tested by biological assay. Further clinical trials are recommended before the leaf can be finally condemned. The negative effect on the mammalian heart under experimental conditions may be overshadowed by the muscle poison effect, and it is suggested that this may not occur when the drug is given by the mouth. Improvements in methods of drying and storage are recommended to get a uniform quality.

Congenital Yaws (B. N. Bandyopadhyay).—Contrary to general opinion, the author thinks that many of the cases of yaws in infants are of a congenital nature. During the last six years he has come across the disease in the Native Civil Hospital, Kakemega, Kenya Colony, in people of all ages from 2 days to 80 years. In one case the baby was 2 weeks old and the mother had suffered from yaws six months previously and was treated by the author. The father had had syphilis six years previously. He had two healthy children born of his first wife, and the baby in question suffering from yaws was the child of his second wife. This case is considered of probable congenital transmission.

NORTH PERSIAN FORCES MEMORIAL MEDAL.

Dr. W. Corner, O.B.E., M.D., Iraq Health Service, has been awarded the North Persian Forces Memorial Medal for the year 1925 for his paper "Malaria in the Kirkuk Division of Northern Mesopotamia during 1923," published in the *Transactions of the Royal Society of Tropical Medicine and Hygiene*, 1925, vol. 19, Nos. 1 and 2, pp. 41-69.

This is the third award of the medal, which, in accordance with the terms of the Trust Deed of the Memorial Fund, is awarded annually for the best paper on Tropical Medicine or Hygiene published in any journal during the preceding twelve months by any medical officer of under twelve years' service of the Royal Navy, Royal Army Medical Corps, Royal Air Force, Indian Medical Service or of the Colonial Service, provided the Memorial Committee consider that any of the papers published has attained a standard of merit justifying an award.

Correspondence.

To the Editor of the JOURNAL OF TROPICAL MEDICINE AND HYGIENE.

SIR,—Professor Ziemann's note (objecting to my review on his "Malaria and Blackwater Fever,") published in English in the JOURNAL OF TROPICAL MEDICINE AND HYGIENE of March 15, 1926, was submitted in German to the Editor of the *Tropical Diseases Bulletin*, for his private (persönlich) information. On its unexpected appearance elsewhere I have with care reconsidered the original volume, my review thereon which Professor Ziemann has seemingly imperfectly understood, and his own published note.

Taking into full consideration the often unpleasant duty which an honest critic owes to the *Bulletin's* readers and his obligation towards the author to furnish no criticism that is not fair and just, I have reached the deliberate opinion that the notice, to which objection is taken, requires no alteration. With confidence I leave this conclusion in the hands of such as are sufficiently interested in the matter to undertake the requisite comparisons for themselves.

I am,

"*Heathfield*," Yours truly,
Castlebar Park,
Ealing, *W.* 5. CLAYTON LANE.
April 8, 1926.

Original Communication.

FURTHER OBSERVATIONS ON A MYCOLOGICAL METHOD TO IDENTIFY VARIOUS SUGARS AND OTHER CARBON COMPOUNDS.

By ALDO CASTELLANI, C.M.G., M.D., F.R.C.P.,

AND

F. E. TAYLOR, M.D., F.R.C.S., D.P.H.

IN several of the best known manuals of pathology and clinical methods, it is stated that the fermentation test by means of baker's yeast is the only absolutely certain and specific test for glucose.

Since 1904, one of us (A.C.) has called attention to the fallacy of this statement on various occasions, and some years ago we published a paper in which we described a mycological method for the detection of glucose and other carbon compounds, first theoretically devised by one of us (A.C.) in Ceylon. Our results were confirmed by various authorities. Of eight samples of baker's yeast obtained in various quarters of London, and places near London, the following results were obtained:—

Sample 1, when inoculated directly with sugar peptone waters, fermented with production of gas, glucose, levulose, maltose, galactose, saccharose, dextrin, lactose, adonitol, inulin, sorbite, dulcitol, mannitol, raffinose, arabinose, salicin, amygdalin, isodulcitol, erythrite and glycerol.

Sample 2, fermented with production of gas, glucose, levulose, lactose, maltose and saccharose.

Sample 3, fermented with production of gas, glucose, levulose, maltose and galactose; it produced acid but no gas in lactose.

Sample 4, fermented with production of gas, glucose, levulose, maltose, galactose, saccharose, lactose, inulin and dextrin.

Sample 5, fermented with production of gas, glucose, levulose and maltose.

Sample 6, fermented with production of gas, glucose, levulose, maltose and galactose.

Sample 7, fermented with production of gas, glucose, levulose, maltose, galactose, saccharose and lactose.

Sample 8, fermented with production of gas, glucose, levulose, maltose, galactose, saccharose, dextrin, lactose, adonitol, inulin, sorbite, dulcitol, mannitol, raffinose, arabinose, salicin, amygdalin, isodulcitol, erythrite and glycerol.

Usually the ordinary samples of baker's yeast, as shown by one of us (A. C.) some years ago, are not pure; they consist of one or two species of saccharomyces, with almost constantly a Gram-positive bacillus and other bacteria. We therefore obtained cultures of pure yeast from the laboratories of well-known yeast firms. Of three cultures so obtained, one fermented with the production of gas, glucose, levulose, galactose and saccharose; the other two fermented maltose in addition to these sugars.

When urine is fermented by baker's yeast we cannot, therefore, come definitely to the conclusion that the fermentable substance is glucose; it might be galactose, maltose, or other sugars. To detect glucose, recourse should be made to really specific germs for that sugar; i.e., germs that will ferment glucose only with the production of gas and no other carbohydrate.

Such organisms exist but are extremely rare, because, in our experience, when an organism ferments glucose, with the production of gas, it will, as a rule, also ferment levulose and frequently other sugars and carbohydrates. One of the few germs that ferment glucose only, with production of gas, is *Monilia balcanica*, found by one of us (A.C.) some years ago; this monilia we unfortunately lost, together with other interesting fungi, in an accidental fire.

In the absence of *Monilia balcanica*, the next best organism to use instead of ordinary yeast is *Monilia krusei* Castellani. This monilia ferments, with the production of gas, glucose and levulose only. If a urine is fermented by it, we can conclude with certainty that it contains either glucose or levulose, or a mixture of the two. For practical purposes, therefore, it is much more suitable than baker's yeast which will, as a rule, ferment a large number of sugars, including maltose, galactose, saccharose and lactose.

MYCOLOGICAL METHOD TO IDENTIFY VARIOUS SUGARS AND OTHER CARBON COMPOUNDS.

As stated in previous publications, we do not possess specific germs for each substance, microorganisms which will ferment maltose, galactose or inulin only, but as there are a number of species of hyphomycetes and bacteria which select certain carbohydrates to the exclusion of others, we have found it possible, by using certain of these hyphomycetes and bacteria and comparing the results, to devise a general method. To understand the working of the method it is necessary to keep in mind the biochemical fermentative characters of certain fungi and bacteria, which are collected in table 1.

We will limit ourselves to describing briefly the identification and detection of maltose, galactose and inulin, and we will also give a list of the principal mycological formulæ we have devised and employed in the identification of various other carbon compounds.

Identification of Maltose.—In order to determine whether a given substance is maltose or not, a sterile 1 per cent. solution in sugar-free peptone water is made and distributed into two tubes, each containing a Durham's fermentation tube or similar appliance. One of the following procedures is then used:—

(*A*) A 1 per cent. sterile solution in sugar-free peptone water is made of the substance to be tested for maltose. The solution is distributed into two tubes, which are labelled 1 and 2. Tube 1 is inoculated with *Monilia tropicalis* and tube 2 with *Monilia macedoniensis*, or other monilias of the same group (*Monilia macedoniensoides*). If, after four days' incubation at 37° C., tube 1 contains gas and tube 2 does not, we can come to the conclusion that the substance is maltose. This is easily understood if we keep in mind the biochemical reactions of the two monilias. *Monilia tropicalis* ferments, with the production of gas, the following substances: glucose, levulose, galactose, maltose and saccharose. *Monilia macedoniensis* and all other monilias of the macedoniensis group (*Monilia macedoniensoides*, &c.) ferment, with the production of gas, the following carbon compounds: glucose, levulose, galactose, saccharose and inulin. The substance we are investigating has been fermented, with the production of gas, by *Monilia tropicalis*. It can be, therefore, only glucose, levulose, maltose, galactose or saccharose; but if

In the tables and in the mycological formulas + indicates gas; O = absence of gas; simple acid fermentation is not taken into account.

it had been glucose, levulose, galactose or saccharose, it would have been fermented with production of gas by *Monilia macedoniensis* also. Therefore, it can only be maltose.

Monilia tropicalis Castellani ... ... + } — Maltose.
Monilia macedoniensis Castellani ... O }

(*B*) Tube 1 is inoculated with *Monilia pinoyi* and tube 2 with *Monilia krusei*. The two tubes are placed in an incubator at from 35° to 37° C. for four days. If, after that time, tube 1 (*Monilia pinoyi*) contains gas and tube 2 (*Monilia krusei*) does not, we can come to the conclusion that the substance is maltose. This is easily understood by keeping in mind the fermentative reactions of the

monilias. *Monilia pinoyi* ferments, with the production of gas, the following compounds only: glucose, levulose, and maltose. *Monilia krusei* ferments, with the production of gas, glucose and levulose only. Our substance has been fermented, with the production of gas, by *Monilia pinoyi;* it can be only glucose, levulose or maltose, but if it had been either glucose or levulose it would have been fermented also by *Monilia krusei;* therefore, it can only be maltose.

(*C*) Tube 1 is inoculated with *Monilia metalondinensis* and tube 2 with *Monilia macedoniensis* or *Monilia macedoniensoides*. The two tubes are incubated at 37° C. for four days. If after that time tube 1 contains gas and tube 2 does not, the substance is maltose. This is explained by the fact that *Monilia metalondinensis* ferments, with the production of gas, only glucose, levulose, maltose and galactose; and *Monilia macedoniensis* only the following carbon compounds: glucose, levulose, galactose, saccharose and inulin. The substance we are investigating has been fermented by *Monilia metalondinensis*. It can be, therefore, only glucose, levulose, maltose or galactose; but if it were glucose, levulose or galactose, it would have been fermented also by *Monilia macedoniensis*. There is only one possibility left—it must be maltose.

Monilia metalondinensis Castellani ... + } = Maltose.
Monilia macedoniensis Castellani ... 0 }

Identification of Maltose when Present with Other Common Fermentable Substances (Glucose, Levulose, Galactose, Saccharose).—If a liquid is suspected of containing maltose mixed with glucose, levulose, galactose and saccharose, it is fermented with *Monilia macedoniensis* or *Monilia macedoniensoides*. If after exhaustion with *Monilia macedoniensis* the liquid is still fermented, with the production of gas, by *Monilia pinoyi, Monilia tropicalis* or *Monilia metalodinensis,* the conclusion is that the liquid also contains maltose. Strains of the various monilias should be used which have approximately the same fermentative power on the various carbohydrates they all ferment.

Identification of Galactose.—In determining whether or not a certain substance is galactose, the following procedures are used:—

(*A*) A 1 per cent. sterile solution of the substance is made in sugar-free peptone water and distributed into two tubes, each containing a fermentation tube. Tube 1 is inoculated with *Monilia metalondinensis* and tube 2 with *Monilia pinoyi*. If, after four days' incubation at 37° C. tube 1 contains gas and tube 2 does not, the substance must be galactose. The explanation lies in the fact that *Monilia metalondinensis* ferments only the following carbon compounds: glucose, levulose, maltose and galactose. *Monilia pinoyi* ferments only the following substances: glucose, levulose and maltose. The substance has been fermented by *Monilia metalondinensis*. It can be, therefore, only glucose, levulose, maltose or galactose. It has not been fermented by *Monilia pinoyi,* so it cannot be glucose, levulose or maltose. There is only one possibility left—it must be galactose.

Monilia metalondinensis ... ... + } = Galactose.
Monilia pinoyi ... ... 0 }

(*B*) The solution is distributed into three tubes, each containing a fermentation tube. Tube 1 is inoculated with *Monilia metalondinensis,* tube 2 with *Monilia krusei,* and tube 3 with *Monilia macedoniensis*. The three tubes are placed in an incubator at 37° C. for four days. If, after that period of time, tubes 1 and 3 contain gas and tube 2 does not, the substance is galactose.

This is easily explained by keeping in mind the biochemical reactions of the three fungi. *Monilia metalondinensis* produces gas only in glucose, levulose, maltose and galactose; *Monilia macedoniensis* produces gas only in glucose, levulose, galactose, saccharose and inulin; *Monilia krusei* produces gas only in glucose and levulose. The substance we are investigating has been fermented, with the production of gas, by *Monilia metalondinensis*. It can be, therefore, only glucose, levulose, maltose or galactose. It cannot be glucose or levulose, because in such a case it would have been fermented also by *Monilia krusei,* and it cannot be maltose, because it would not have been fermented by *Monilia macedoniensis*. There is only one possibility left—it must be galactose.

Monilia metalondinensis ... ... + }
Monilia krusei ... ... 0 } = Galactose.
Monilia macedoniensis ... ... + }

(*C*) The solution is distributed into three tubes: tube 1 is inoculated with *Monilia macedoniensis,* tube 2 with *Monilia krusei,* and tube 3 with *Bacillus paratyphosus* B. Schottmüller. If, after four days in the incubator at 37° C., tube 1 shows presence of gas, tube 2 shows absence of gas, and tube 3 shows presence of gas, we can come to the conclusion that the substance we are investigating is galactose. As the substance has been gas-fermented by *Monilia macedoniensis* it can only be glucose, levulose, galactose, saccharose or inulin; but it has not been fermented by *Monilia krusei,* therefore it cannot be glucose or levulose. It can only be galactose, saccharose or inulin, but if it had been saccharose or inulin it would have been fermented by *Bacillus paratyphosus* B. There is only one possibility left—it must be galactose.

Monilia macedoniensis Castellani ... + }
Monilia krusei ... ... 0 } = Galactose.
Bacillus paratyphosus B Schottmüller + }

(*D*) The solution is distributed into two tubes: tube 1 is inoculated with *Bacillus morgani* (strain S) and tube 2 with *Monilia krusei*. If, after three days in the incubator at 35° C., tube 1 contains gas and tube 2 does not, we can come to the conclusion that the substance is galactose.

This is easily understood by keeping in mind the fermentative reactions of the two germs. *Bacillus morgani* (strain S) ferments, with production of gas, only glucose, levulose and galactose, and *Monilia krusei* only glucose and levulose. The substance we are investigating has been fermented, with production of gas, by *Bacillus morgani;* it can only be glucose, levulose or galactose. It has not been fermented by *Monilia krusei;* it cannot, therefore, be glucose or levulose; it must be galactose.

Bacillus morgani Castellani and Chalmers + } = Galactose.
Monilia krusei Castellani ... ... 0 }

Identification of Galactose when Present with other Common Fermentable Substances (Glucose, Levulose, Maltose, Saccharose).—To detect galactose in a liquid in which it is suspected to be present together with glucose, levulose, maltose or saccharose, the liquid is inoculated with an organism which gas-ferments all the sugars we have mentioned except galactose, for instance *Monilia bronchialis*. If after exhaustion with *Monilia bronchialis* the liquid is still fermentable with *Monilia pinoyi* or *Monilia tropicalis,* the inference is that the liquid contained galactose in addition to other fermentable substances.

Identification of Inulin.—In determining whether a substance is inulin or not, a sterile 1 per cent. solution in sugar-free peptone water is made and distributed into two tubes, each containing a Durham's fermentation tube or similar appliance. The following procedure is then used:—

(*A*) Tube 1 is inoculated with *Monilia macedoniensis* or any other monilia of the same group, such as *Monilia macedoniensoides* or *Monilia chalmersi,* and tube 2 with *Monilia tropicalis*. The two tubes are placed in an incubator at from 35° to 37° C. for four days. If, after that time, tube 1 contains gas and tube 2 does not, we can come to the conclusion that the substance is inulin. This is easily understood by keeping in mind the fermentative reactions of the two monilias. *Monilia macedoniensis* and all other monilias of the same group ferment, with the production of gas, only the following carbon compounds: glucose, levulose, galactose, saccharose and inulin. *Monilia tropicalis* Castellani ferments, with the

production of gas, only glucose, levulose, maltose, galactose and saccharose.

Monilia macedoniensis Castellani ... + } = Inulin.
Monilia tropicalis Castellani ... ... 0 }

(*B*) Tube 1 is inoculated with *Monilia macedoniensis* Castellani and tube 2 with *Monilia rhoi* Castellani. The two tubes are placed in an incubator at from 35° to 37° C. for four days. If after that time tube 1 contains gas and tube 2 does not, we can come to the conclusion that the substance is inulin. This is easily understood when we remember that *Monilia macedoniensis* ferments, with the production of gas, only glucose, levulose, galactose, saccharose and inulin, and *Monilia rhoi* ferments, with the production of gas, only glucose, levulose, galactose and saccharose.

Monilia macedoniensis Castellani ... + } = Inulin.
Monilia rhoi Castellani ... ... 0 }

(*C*) Tube 1 is inoculated with *Monilia macedoniensis* and tube 2 with *Bacillus pseudocoli* or *Bacillus neapolitanus*, or any other strain of the communior group of *Bacillus coli* (ferment saccharose). The tubes are incubated at 37° C. for four days. If after that time tube 1 contains gas and tube 2 does not, we can come to the conclusion that the substance, according to all probabilities, is inulin, since glucose, levulose, galactose and saccharose would have been fermented also by *Bacillus pseudocoli* or *Bacillus neapolitanus* or any other strain of the *Coli communior* group.

Monilia macedoniensis Castellani... ... + }
Bacillus coli communior Escherich; } = Inulin.
Bacillus pseudocoli Castellani; *Bacillus neapolitanus* Emmerich, &c. ... ... 0 }

(*D*) Tube 1 is inoculated with *Monilia macedoniensis* Castellani and tube 2 with *Bacillus asiaticus* Castellani. The two tubes are placed in an incubator at 37° C. for four days. If after that time tube 1 contains gas and tube 2 does not, we can come to the conclusion that the substance, according to all probabilities, is inulin. This is easily understood by remembering the fermentative reactions of the two organisms. *Monilia macedoniensis* ferments only glucose, levulose, galactose, saccharose and inulin, with production of gas; while glucose, levulose, galactose and saccharose are also fermented by *Bacillus asiaticus;* the substance must, therefore, be inulin.

Monilia macedoniensis Castellani .. ... + } = Inulin.
Bacillus asiaticus ... . 0 }

Identification of Inulin when Present with other Fermentable Substances.—If we suspect that a liquid contains inulin mixed with one or several of the following fermentable substances, viz., glucose, levulose, maltose, galactose, saccharose, mannitol, lactose, dextrin, raffinose, arabinose, sorbitol, glycerol, salicine and isodulcitol, we can ascertain its presence in the following manner: The liquid is fermented with *Bacillus coli communior*. If, after exhaustion with *Bacillus coli communior* the liquid can still be fermented with *Monilia macedoniensis*, with the production of gas, the inference is that it contained inulin. The precaution should be taken to select a strain of *Bacillus coli communior*, the fermentative power of which on glucose, levulose, galactose and saccharose is not less than that of *Monilia macedoniensis*.

Use of the Mycologic Method in Urine Analysis.

From numerous experiments we have carried out, by adding to samples of urine various sugars and other carbohydrates, and also from a fairly large number of pathological specimens, we have determined that the method can be used in urine analysis for the detection and differentiation of certain sugars and other carbon compounds, such as glucose, maltose, galactose, lactose and pentose, provided the amount of such substances present is not too minute (not less than 0·1 per cent.). The urine is distributed in sterile tubes, containing Durham's fermentation tubes or similar devices, or ordinary saccharometers may be used; they are inoculated with the organisms already mentioned. Two points of considerable importance are:—

(1) The urine must be aseptic; if it cannot be collected aseptically it should be sterilized as soon as possible, before or after distribution in the sterile tubes, by heating in Koch's steamer for thirty minutes; once is sufficient for practical purposes, but in special cases it may be heated on two or three consecutive days. It should never be autoclaved, as this procedure may alter the characters of the sugars and other carbohydrates present. Another procedure is to filter the sample of urine by means of a Chamberland or a Berkefeld filter.

(2) It is of great advantage to add a third or an equal amount of peptone water to the urine, otherwise the organisms may, at times, grow very scantily, and there may be no distinct production of gas.

If a urine is Fehling-reducing, we can determine which of the commonest sugars found in pathological urines is present (glucose, levulose, maltose, galactose, lactose, pentose) by the following procedure:—

The urine is distributed into six tubes, each containing a Durham's fermentation tube. They are labelled 1, 2, 3, 4, 5 and 6. Tube 1 should be inoculated with *Monilia balcanica* Castellani, or *Monilia parabalcanica* Castellani; tube 2 with *Monilia krusei* Castellani; tube 3 with *Monilia pinoyi* Castellani; tube 4 with *Monilia metalondinensis* Castellani; tube 5 with *Bacillus coli communior* Escherich, and tube 6 *Bacillus paratyphosus* B Schottmüller.

After the tubes are incubated at 35° C. for four days, the results are read:—

(1) If in tubes 1, 2, 3, 4, 5 and 6 gas is present, the reducing substance is glucose.

(2) If tube 1 contains no gas, and in tubes 2, 3, 4, 5 and 6 gas is present, the reducing substance is levulose.

(3) If tubes 1 and 2 contain no gas, and in tubes 3, 4, 5 and 6 gas is present, the reducing substance is maltose.

(4) If tubes 1, 2 and 3 contain no gas, and in tubes 4, 5 and 6 gas is present, the reducing substance is galactose.

(5) If tubes 1, 2, 3 and 4 contain no gas, and in tubes 5 and 6 gas is present, the reducing substance is pentose.

(6) If tubes 1, 2, 3, 4 and 5 contain no gas, and in tube 6 gas is present, the reducing substance is lactose.

(7) If none of the tubes contains gas, the reducing substance belongs to the non-fermentable group of reducing substances, including uric acid, creatinine, hippuric acid, and others.

Presence in the Urine of More Than One Reducing Substance.—If the presence of more than one sugar and other carbohydrates is suspected, this may, to a certain extent, be ascertained and the various carbohydrates determined by our mycological method. If the urine, for instance, after exhaustion with *Monilia krusei* is still fermented by *Monilia tropicalis* or *Monilia metalondinensis*, but not by *Monilia macedoniensis*, we

may come to the conclusion that the urine contained maltose in addition to glucose or levulose or both. If the urine after exhaustion with *Monilia balcanica* is still fermented by *Monilia krusei*, the inference is that the urine contained levulose in addition to glucose. If after exhaustion first with *Monilia balcanica* Castellani and then with *Monilia krusei* Castellani the urine is fermentable, with production of gas, by *Bacillus morgani* Castellani and Chalmers, the presumption is that it contained three sugars—glucose, levulose and galactose. The explanation is found in the fact that with regard to Fehling-reducing substances, *Monilia balcanica* Castellani ferments, with the production of gas, glucose only; *Monilia krusei* Castellani, glucose and levulose; *Bacillus morgani* Castellani and Chalmers, glucose, levulose and galactose. If a Fehling-reducing urine after exhaustion with *Monilia krusei* is capable of being fermented by *Bacillus coli* and not by *Bacillus paratyphosus* B, the inference is that the urine contained lactose in addition to glucose or levulose or both.

TABLE 2.—IDENTIFICATION OF CERTAIN FEHLING-REDUCING SUBSTANCES.

[1] The reducing substance is made into a 1 per cent. peptone water solution. Selected strains of the various organisms with permanent biochemical reactions and producing a large amount of gas should be used.

Maltosuria.—Maltose, as is well known, reduces Fehling and cases of maltosuria have naturally been mistaken for true glycosuria. For the detection of maltose, the urine is obtained aseptically by catheter, or if this is not feasible is collected in a sterile receptacle and distributed at once in sterile tubes, each containing a small fermentation tube. The tubes are sterilized in Koch's stove for thirty minutes once or twice at an interval of six hours. This, in our experience, is generally sufficient, but at times it is advisable to repeat the sterilization in Koch's stove on two or three consecutive days. The urine should never be autoclaved, as this procedure may alter the composition of the sugars and other carbohydrates present. The urine freshly passed may also be filtered through a Chamberland instead of being sterilized. The tubes of aseptic urine are inoculated with the monilias, as explained above. If it is suspected that maltose is present in conjunction with other fermentable substances, such as glucose, levulose and galactose, the urine is exhausted with *Monilia macedoniensis*. If, after exhaustion with *Monilia macedoniensis*, the urine is still fermentable when inoculated with *Monilia tropicalis* or *Monilia metalondinensis* or *Monilia pinoyi*, we can come to the conclusion that the urine contains maltose in addition to other fermentable substances.

Illustrative Case.—Among the several cases of maltosuria we have come across we may quote the following which we observed a few years ago: Englishman, aged 47, tea planter. Has been a heavy beer drinker for many years. He is feeling quite well, except that his stoutness

TABLE 3.—KEY TO THE IDENTIFICATION OF CERTAIN FEHLING-REDUCING SUBSTANCES.

makes it difficult for him to go for long walks, and this interferes with his duties. A Fehling-reducing substance was found in his urine several times during the previous five years by various doctors, and he was told that he had glycosuria and might develop true diabetes. He came to consult one of us. The urine was Fehling-reducing and was investigated for presence of the following Fehling-reducing carbohydrates: glucose, levulose, galactose, maltose, lactose, pentose. The patient passed urine, in our presence, into two sterile vessels; the urine of the second vessel was distributed immediately by means of a sterile pipette into five tubes of peptone water (two parts of urine to one of peptone water), each containing a fermentation tube. The tubes were labelled Nos. 1 to 5. No. 1 was inoculated with *Monilia krusei* Castellani, No. 2 with *Monilia pinoyi* Castellani, No. 3 with *Monilia metalondinensis* Castellani, No. 4 with *Bacillus coli* Escherich, and No. 5 with *Bacillus paratyphosus* B Schottmüller. The five tubes were placed in the incubator at 37° C. for four days. On examination the results were as follows:—

Tube No. 1	(*Monilia krusei*)	O
,, 2	(*Monilia pinoyi*)	+
,, 3	(*Monilia metalondinensis*) ...	+
,, 4	(*Bacillus coli*)	+
,, 5	(*Bacillus paratyphosus* B) ...	+

This result according to our method means presence of *maltose*. The urine was gas-fermented by *Monilia pinoyi* and not by *Monilia krusei*. *Monilia pinoyi* produces gas only in three carbon compounds, viz., glucose, levulose and maltose. The urine therefore must contain either glucose or levulose or maltose or a mixture of these various sugars, but if the urine contained either glucose or levulose it would have been gas-fermented also by *Monilia krusei*. The sugar present must therefore be maltose. We may add that the result obtained by our mycological method was confirmed by the carrying out of purely chemical methods by a well-known chemist.

Lactosuria.—Next to glucose, lactose is the commonest sugar found in the urine. It is frequently met with in the urine of nursing mothers. Lactose, as is well known, reduces Fehling's solution, and not infrequently lactosuria has been mistaken for true glycosuria. It is most important to distinguish between the two conditions, as lactosuria is not a very serious condition, while glycosuria especially in nursing women, is of grave prognosis. The chemical detection and determination of lactose is difficult for an ordinary medical man. In most text-books it is stated that if a urine reduces Fehling, and is not fermented by ordinary baker's yeast (so-called German yeast), the presumption is that the reducing substance is lactose. There are, however, two very important sources of error.

First, quite a number of specimens of baker's yeast ferment lactose in addition to glucose, maltose and other sugars; second, even if the baker's yeast should not ferment lactose, this is not the only Fehling-reducing substance which may not be fermented by baker's yeast—pentose, for instance.

If a urine which reduces Fehling is not fermented by ordinary yeast we cannot, therefore, come to the conclusion that it is a case of lactosuria.

Detection and Determination of Lactose by the Mycological Method.—This method can be carried out in various ways. Herewith a few mycological formulæ as examples.

I.—In a Fehling-reducing urine, for practical purposes, the following formula is correct:—

Bacillus coli Escherich	+	= Lactose.
Bacillus paratyphosus B Schottmüller ...	O	

Bacillus coli and *Bacillus paratyphosus* B, besides lactose differ in their action on raffinose and salicin and glycerol, but raffinose and salicin are not carbon compounds found in the urine and at any rate they are not Fehling-reducing. The same formula applies to raffinose, salicin and glycerol, but there are substances which are of very rare occurrence in the urine and, moreover, they are not Fehling-reducing, and therefore this formula may be considered to be specific for practical purposes.

II.—*Bacillus neapolitanus* Emmerich ...	+	= Lactose.
Bacillus pseudoasiaticus Castellani	O	

The explanation lies in the fact that *Bacillus neapolitanus* and *Bacillus pseudoasiaticus* differ only in lactose as regards sugars and other carbohydrates found in pathological urines.

III.—*Monilia metalondinensis* Castellani	O	= Lactose (with great probability).
Bacillus coli Escherich	+	
Bacillus paratyphosus B Schottmüller	O	

The technical details for carrying out the test are identical with those already mentioned in connection with the search for maltose, &c.

Pentosuria.—Pentosuria is not a very rare condition. As is well known, the pentoses reduce Fehling well and Nylander solution very little; they give a positive reaction with Bial's and Read's modifications of the orcein test.

The mycological method can be used for the detection of pentose in a Fehling-reducing urine according to the following formulæ:—

Monilia tropicalis	O	= Pentose (generally arabinose).
Bacillus coli Escherich	+	
Bacillus paratyphosus B	+	

Monilia metalondinensis	O	= Pentose (generally arabinose).
Bacillus coli Escherich	+	
Bacillus paratyphosus B	+	

Illustrative Case.—Some time ago one of us was consulted by a planter, 38 years of age, who had been sent home from a tropical country in the Far East, with the diagnosis of diabetes. His general condition, however, was fairly good, and he said he had not lost much weight. According to his statements he was not very thirsty or very hungry, nor did he feel very weak. He appeared, however, somewhat nervy and irritable, and was very worried at the idea of suffering from diabetes. The urine passed during the twenty-four hours varied between three and four pints. It was slightly acid, density 1,020. It persistently reduced Fehling well, and apparently the diagnosis of diabetes had been based on this fact.

The urine was examined by the mycological method for presence of the following Fehling-reducing carbohydrates: glucose, levulose, galactose, maltose, pentose, lactose. The patient was made to pass urine into three sterile vessels; the urine of the second vessel was distributed immediately by means of a sterile pipette in six tubes of peptone water (about two parts of urine to one of peptone water), each containing a fermentation tube. The tubes were labelled Nos. 1 to 5. Tube 1 was inoculated with *Monilia krusei* Castellani; tube 2 with *Monilia pinoyi* Castellani; tube 3 with *Monilia metalondinensis* Castellani; tube 4 with *Bacillus coli* Escherich; tube 5 with *Bacillus paratyphosus*

B Schottmüller. The five tubes were placed in the incubator at 37° C. and examined after forty-eight hours. The following were the results :—

Tube 1	*Monilia krusei* Castellani	O
„ 2	*Monilia pinoyi* Castellani	O
„ 3	*Monilia metalondinensis* Castellani ...	O
„ 4	*Bacillus coli* Escherich	+
„ 5	*Bacillus paratyphosus* B Schottmüller ...	+

According to our method these results in a Fehling-reducing urine mean presence of pentoses.

The result obtained by our mycological test was confirmed by chemical investigation. The urine which reduced Fehling well and Nylander solution very little gave a positive reaction for pentoses with Bial's and Read's modifications of the orcein test. There can be very little doubt, therefore, that the patient was suffering from "pentosuria" and not from diabetes. It is important in practice to try to differentiate in every case between glycosuria and pentosuria, as the first condition is often of grave prognosis, while the second points to a much more benign disturbance of metabolism and practically requires no treatment. We are inclined to believe that our method will facilitate making such a differentiation a matter of routine.

Saccharosuria.—Spontaneous saccharosuria is an extremely rare condition, but artificial saccharosuria is not so rare among the malingerers. During the Great War we came across three cases in which saccharose had been added to the urine with the object of misleading the medical officer. The doctor who uses as routine the usual Fehling method is not apt to diagnose such cases as glycosuria, as saccharose does not reduce, at any rate not very clearly, Fehling's solution; but the medical man who uses what is considered, by most authorities, the more exact method of yeast fermentation will very likely fall into error, because though in so many textbooks it is stated that glucose is the only substance fermented by ordinary baker's yeast, we have found that a very large number of specimens of baker's yeast will ferment saccharose and also levulose, maltose, &c., in addition to glucose.

Mycological Tests to Determine Saccharose.—According to our method various tests may be evolved to determine whether a certain carbohydrate of those found in pathological urine is or is not saccharose; we give here a few of these tests in the convenient shape of mycological formulæ :—

I.—*Monilia metalondinensis* Castellani O
Monilia tropicalis Castellani ... + } = Saccharose.

This is explained by the fact that *Monilia metalondinensis* and *Monilia tropicalis* are identical in all their biochemical reactions except on saccharose, which is fermented with production of gas by *Monilia tropicalis* and not fermented by *Monilia metalondinensis*.

II.—*Monilia pinoyi* Castellani ... ... O
Monilia rhoi Castellani ... ... + } = Saccharose.

The explanation lies in the fact that *Monilia pinoyi* ferments with production of gas only glucose, levulose, maltose, and *Monilia rhoi* only glucose, levulose, maltose and saccharose. If a substance therefore is not fermented by *Monilia pinoyi* and is fermented with production of gas by *Monilia rhoi*, it must be saccharose.

To the above purely mycological formulæ we add a chemico-mycological formula which may be found useful in practice :—

Fehling ... ... O
Monilia tropicalis Castellani ... ... + } = Saccharose.

This is explained by the fact that *Monilia tropicalis* ferments with production of gas glucose, levulose, maltose, saccharose, and no other substance. If Fehling is negative it cannot be any of the first three substances, as they are all Fehling-reducing, and it must therefore be saccharose.

Detection of Saccharose when Mixed with Other Fermentable Substances.—Exhaust the urine with *Bacillus coli* Escherich *sensu stricto* (does not ferment saccharose), and later, after filtration through a Chamberland filter, or prolonged centrifugalization, inoculate it with *Monilia tropicalis*. If the urine is still fermentable the presumption is that in addition to other fermentable substances which can be found by our general method, the urine contains saccharose.

Inosituria.—Inosite, as is well known, does not reduce Fehling; it is not really a sugar, belonging to the aromatic series. It is not of very rare occurrence in the urine; it is, for instance, not infrequently found in diabetes insipidus, but the chemical methods of detecting it are far from easy or rapid. On the other hand, inosite, provided it is present in the urine in not too small a quantity, can be detected and determined with comparative ease by our mycological method.

Two tubes of urine collected aseptically or sterilized as already described, are mixed with one-third, or the same amount, of sugar-free peptone water and inoculated, No. 1 with *Bacillus paratyphosus* B Schottmüller (M variety, which ferments inosite), and No. 2 tube with *Bacillus paratyphosus* A Schottmüller (does not ferment inosite). The two germs, as regards carbohydrates and other pathological substances found in the urine, differ only in their action on inosite. Therefore, if, after forty-eight hours' incubation at 37° C., gas is present in No. 1 tube, and absent in No. 2 tube, we have to deal with inosite. This can be conveniently expressed by the following formula :—

Bacillus paratyphosus B Schottmüller, var. M +
Bacillus paratyphosus A Schottmüller ... O } = Inosite.

If the result of the test is :—

Bacillus paratyphosus B Schottmüller, var. M O
Bacillus paratyphosus A Schottmüller ... O

it means that the substance is neither inosite nor any other substance fermentable by *Bacillus paratyphosus* B, var. M, or *Bacillus paratyphosus* A, hence it cannot be glucose, levulose, maltose, saccharose, &c.

If the result of the test is :—

Bacillus paratyphosus B Schottmüller, var. M +
Bacillus paratyphosus A Schottmüller ... +

exhaust the urine with *Bacillus paratyphosus* A, and then inoculate with *Bacillus paratyphosus* B, var. M, using strains having approximately the same fermentation power. If gas is produced, the in-

ference is that the urine contained inosite in addition to other fermentable substances, which can be determined by using our general method.

Summary.

The whole subject can be condensed into the following formulæ:—

Mycologic Formulæ.

Glucose.

Monilia balcanica Castellani ... + = Glucose.

Levulose.

Monilia krusei Castellani ... ... + }
Monilia balcanica Castellani ... O } = Levulose.

Maltose.

Monilia tropicalis Castellani ... +
Monilia macedoniensis (*Monilia macedoniensoides*) Castellani ... O } = Maltose.

Monilia metalondinensis Castellani +
Monilia macedoniensis Castellani or *Monilia macedoniensoides* ... O } = Maltose.

Monilia pinoyi Castellani ... +
Monilia krusei Castellani ... O } = Maltose.

Monilia pinoyi Castellani ... +
Monilia macedoniensis (*Monilia macedoniensoides*) Castellani ... O } = Maltose.

Monilia tropicalis Castellani ... +
Monilia rhoi Castellani ... ... O } = Maltose.

Monilia pinoyi Castellani ... +
Bacillus morgani Castellani and Chalmers ... ... O } = Maltose.

Monilia metalondinensis Castellani +
Bacillus morgani Castellani and Chalmers ... ... O } = Maltose.

Galactose.

Monilia metalondinensis Castellani +
Monilia pinoyi Castellani ... O } = Galactose.

Monilia metalondinensis Castellani +
Monilia krusei Castellani ... O = Galactose.
Monilia macedoniensis Castellani +

Monilia tropicalis Castellani ... +
Monilia bronchialis Castellani ... O } = Galactose.

Monilia tropicalis Castellani ... +
Monilia macedoniensis Castellani +
Monilia krusei Castellani ... O } = Galactose.
Bacillus paratyphosus B Schottmüller ... ... +

Bacillus morgani Castellani and Chalmers ... ... + } = Galactose.
Monilia krusei Castellani ... O

Saccharose.

Monilia tropicalis Castellani ... +
Monilia metalondinensis Castellani O } = Saccharose.

Monilia tropicalis Castellani ... +
Bacillus coli communis, sensu stricto (does not ferment saccharose) Escherich ... ... O } = Saccharose.

Monilia tropicalis Castellani ... +
Bacillus paratyphosus B Schottmüller ... ... O } = Saccharose.

Monilia macedoniensis Castellani +
Bacillus coli communis, sensu stricto Escherich ... ... O = Saccharose.
Bacillus coli communior ... ... +

Monilia macedoniensis Castellani +
Bacillus paratyphosus B Schottmüller ... ... O } = Saccharose.
Bacillus coli communior ... ... +

Bacillus coli communis, sensu stricto Escherich ... ... O } = Saccharose.
Bacillus neapolitanus Emmerich +

Bacillus coli communis, sensu stricto Escherich ... ... O } = Saccharose.
Bacillus asiaticus Castellani ... +

Inulin.

Monilia macedoniensis (*Monilia macedoniensoides*) Castellani ... + } = Inulin.
Monilia tropicalis Castellani ... O

Monilia macedoniensis (*Monilia macedoniensoides*) Castellani ... + } = Inulin.
Monilia rhoi Castellani ... ... O

Monilia macedoniensis (*Monilia macedoniensoides*) Castellani ... +
Bacillus coli communior Escherich; or *Bacillus pseudocoli* Castellani; or *Bacillus neapolitanus* Emmerich ... ... O } = Inulin.

Monilia macedoniensis (*Monilia macedoniensoides*) Castellani ... + } = Inulin.
Bacillus asiaticus Castellani ... O

Inositol.

Bacillus paratyphosus B (var. M) Schottmüller ... ... + } = Inositol (with great probability).
Bacillus paratyphosus A Schottmüller ... ... O

Glycerol.

Bacillus asiaticus Castellani ... +
Bacillus paratyphosus B (var. M) Schottmüller ... ... O } = Glycerol.
Bacillus columbensis (strain L) Castellani ... ... +

Chemicomycologic Formulæ.

Saccharose.

Fehling ... ... O } = Saccharose.
Monilia tropicalis Castellani ... +

Lactose.

Fehling ... ... +
Bacillus paratyphosus B Schottmüller ... ... O } = Lactose.
Bacillus coli communis Escherich +

Fehling ... ... +
Bacillus orleanensis ... ... +
Monilia macedoniensis ... ... O } = Lactose.
Bacillus coli communis or *communior* ... ... +

Pentose.

Fehling ... ... +
Monilia tropicalis Castellani ... O
Bacillus paratyphosus B Schottmüller ... ... + } = Pentose (generally arabinose).
Bacillus coli communis Escherich +

As is the case with every other biological method, the results must be considered to be relatively and not absolutely certain. It is essential to use only selected strains of the organisms mentioned, with constant characteristics and producing a large amount of gas.

Abridged Method.

The method we now use as a matter of routine is carried out using the following organisms:—

1. *Monilia krusei* Castellani, 1909.
2. *Monilia tropicalis* Castellani, 1909.
3. *Monilia metalondinensis* Castellani.
4. *Monilia macedoniensis* Castellani, 1917. (Var. *macedoniensoides*).
5. *Bacillus morgani* Castellani and Chalmers, 1918.
6. *Bacillus coli communis* Escherich, 1886, *sensu stricto* (does not ferment saccharose).
7. *Bacillus coli communior* Escherich-Durham, 1899 (var. *pseudo-coscoroba*).
8. *Bacillus paratyphosus* B Schottmüller, 1902.
9. *Bacillus columbensis* (strain L) Castellani, 1905.

With the abridged method the following carbohydrates may be easily detected and identified: maltose, galactose, glucose (or levulose) saccharose, lactose, pentose and inulin.

Maltose.

Monilia tropicalis	+	= Maltose
Monilia macedoniensis	O	

Galactose.

Monilia metalondinensis	+	= Galactose.
Monilia krusei	O	
Monilia macedoniensis	+	
Bacillus morgani	+	= Galactose.
Monilia krusei	O	
Monilia macedoniensis	+	= Galactose.
Monilia krusei	O	
Bacillus columbensis (L)	+	
Monilia macedoniensis	+	= Galactose.
Monilia krusei	O	
Bacillus paratyphosus B	+	

Saccharose.

Monilia tropicalis	+	= Saccharose.
Monilia metalondinensis	O	
Monilia tropicalis	+	= Saccharose.
Bacillus paratyphosus B	O	
Monilia tropicalis	+	= Saccharose.
Bacillus coli communis, sensu stricto (does not ferment saccharose)	O	
Monilia tropicalis	+	= Saccharose.
Bacillus columbensis	O	

Inulin.

Monilia macedoniensis (var. *macedoniensoides*)	+	= Inulin.
Monilia tropicalis	O	

Lactose.

Monilia tropicalis	O	= Lactose (with great probability)
Bacillus paratyphosus B Schottmüller	O	
Bacillus coli communis or *Bacillus coli communior*	+	

Glucose and Levulose.

Monilia krusei	+	= Glucose (or levulose).

Chemicomycologic Formulæ.

Saccharose.

Fehling	O	= Saccharose.
Monilia tropicalis	+	

Lactose.

Fehling	+	= Lactose.
Bacillus paratyphosus B	O	
Bacillus coli communis	+	
Fehling	+	= Lactose.
Bacillus paratyphosus B	O	
Bacillus coli communior	+	
Fehling	+	= Lactose.
Bacillus columbensis (L)	O	
Bacillus coli communior	+	

Pentose.

Fehling	+	= Pentose (generally arabinose).
Monilia tropicalis	O	
Bacillus paratyphosus B	+	
Bacillus coli communis or *Bacillus coli communior*	+	

Cultivation of the Monilias kept as Stock Cultures.—The organisms should be grown and kept at 22° C. or at the temperature of the room. Certain monilias, if kept too long in the incubator at 37° C. may lose some of their fermentative characteristics. The best medium is acid glucose agar. Transplant once a month, and from time to time make plates to be certain that the cultures are pure.[1]

Conclusions.

(1) The yeast method, as described in most textbooks of medicine and clinical methods, is not specific for glucose, notwithstanding the statements to that effect. Ordinary samples of baker's yeast, as a rule, will ferment levulose, maltose, galactose, saccharose, lactose and many other carbon compounds in addition to glucose. When a sample of urine is fermented by ordinary yeast we cannot come to the conclusion that the urine contained glucose, as it might have contained maltose, galactose, lactose or other sugars.

(2) For the identification of glucose and its detection in the urine, a germ should be used which ferments glucose only. Such an organism is *Monilia balcanica* Castellani. When *Monilia balcanica* for some reason is not obtainable, the next best organism is *Monilia krusei* Castellani, which ferments glucose and levulose only, and does not affect maltose, galactose, lactose or any other carbon compound. When a urine is fermented by *Monilia krusei*, it contains with certainty either glucose or levulose or both.

(3) For the identification of various sugars and other carbon compounds, apart from glucose, the mycologic method, first devised by one of us (A.C.) in 1904, in Ceylon, and which we worked out together at King's College Bacteriological Laboratories in London and published in 1917, may be used with advantage. This method seems to be especially useful in the identification of maltose and galactose.

[1] We shall be pleased to supply the necessary bacteria and fungi to workers interested in the subject. Requests for cultures should be sent to the Director, Tropical Department, The Ross Institute, Putney Heath, London.

THE PREVENTION AND TREATMENT OF CHOLERA BY ESSENTIAL OILS.

By J. W. TOMB, O.B.E., M.D., D.P.H.

Chief Sanitary Officer, Asansol Mines Board of Health, Asansol, Bengal, India.

THE Asansol Mining Settlement, which includes the chief coal field of Bengal, is situated in the sub-division of Asansol, at the western end of the district of Burdwan, and lies on either side of the main line running from Calcutta to Delhi, approximately between miles 114 and 144. The settlement, which is about 420 square miles in area, includes 263 collieries and 490 villages, with a total population of 329,353, according to the census of 1924, to which should be added an estimated floating mining population of not less than 100,000. The labour employed in the mining settlement consists chiefly of Sánthâls and Kóls, aboriginal peoples essentially agriculturists by nature, who reside permanently on the land in the districts adjoining the mining settlement but migrate into the settlement in search of work in the coal mines when supplies for any reason run short in their permanent homes, the average duration of their sojourn in the settlement not as a rule exceeding three months on any one occasion. A certain number of these people have, however, become domiciled in the mining settlement on land belonging to some of the larger collieries, and a proportion of mining labour is also drawn from an aboriginal tribe called Bowries indigenous to the mining settlement and permanently resident in the villages within it.

Owing to the fact that the mining settlement lies within the so-called endemic area of cholera in Bengal and to the migratory nature of the labour employed in the coal mines, epidemics of cholera were formerly so frequent and disastrous in this coalfield that at the request of the mining industry the Government of Bengal in 1912 passed the Bengal Mining Settlements Act "to prevent the outbreak and spread of dangerous epidemic disease" in the coalfields of Bengal, the Asansol Mines Board of Health being constituted in 1915 to carry out the provisions of this Act within the area notified as the Asansol Mining Settlement, of which the writer has been the medical officer of health since its inception. The "dangerous epidemic" diseases specifically referred to in the Act are cholera, small-pox and plague; plague, however, is unknown in this part of Bengal in epidemic form. For the prevention and suppression of small-pox in the settlement reliance is successfully placed on the vaccination during the cold weather months of all children born in the settlement during the preceding year and in the revaccination of all contacts when any outbreak of small-pox occurs. The problem of the prevention and suppression of cholera is a more difficult one, since the settlement is constantly exposed to the risk of the introduction of this disease by immigrant labour from without as well as to its dissemination from within. The dissemination of the disease within the settlement is chiefly due to the fact that throughout Bengal the water supply of the people is mainly derived from artificial ponds known as "tanks," the water of which is used indiscriminately by the inhabitants both for washing after defæcation and for drinking. Wells exist in great numbers in the mining settlement, but no uneducated native of the country ever voluntarily drinks well-water until all the ponds or "tanks" in the neighbourhood have become dry. Owing to these circumstances, when once cholera has broken out, it is extremely difficult to check its spread. From investigations at present being carried out by the writer in conjunction with Captain Maitra, I.M.S., of the Calcutta School of Tropical Medicine and Hygiene, it is extremely likely that the endemicity of cholera in Bengal is closely connected with the universality of ground "tanks" as sources of drinking water supply, associated with the insanitary habits and customs of the people and the favourable climatic conditions which enable the comma vibrio to survive in "tanks" throughout the year. In the "Regulations for the Prevention and Treatment of Cholera in the Asansol Mining Settlement" cholera is defined as "any sickness accompanied by vomiting and diarrhœa," and it may be here remarked that continued investigations in the Laboratory of the Mines Board of Health have demonstrated that this definition obtains bacteriological support in over 95 per cent. of cases.

When any case of cholera occurs on a colliery the manager of the colliery is by law required to send immediate notice of the fact by special messenger to the nearest circle-office of the board, which in no instance is situated at a greater distance than five miles away. Similarly, when any case of cholera occurs in a village the relatives of the patient are required by law to give immediate notice of the fact to the chowkidar or village-watchman, who at once notifies the nearest official of the Mines Board of Health. To induce promptitude in the latter case a reward of one rupee (one shilling and sixpence) is paid to the chowkidar for every such notification. The amount of money actually required for this purpose yearly is, however, very small, as when once a single case of cholera has been notified by

a chowkidar the staff of the Mines Board of Health keep in constant touch with the infected village until the epidemic is suppressed. On receiving information of a case of cholera in a village the board's "sanitary assistant" at once proceeds on his bicycle to verify the case and take all necessary steps for the prevention of the spread of the disease. These consist in the sterilization of the dejecta of the patient with some coal-tar disinfectant such as izal, and in the disinfection with chloride of lime of the neighbouring "tank," which, in almost every instance, has been polluted with the patient's excreta, either directly by the patient himself or indirectly by the patient's relatives. A solution of coal tar disinfectant is also left in the infected house in an earthenware vessel for the disinfection of the hands before eating of those actually engaged in nursing the patient. Experience over many years has proved that such measures are usually sufficient to check the extension of the disease in epidemic form, but that they are insufficient to check its spread within the infected house. This is as a rule due to negligence on the part of those attending on patients in not disinfecting or even washing their hands before eating, and also to the wholesale contamination of domestic utensils, both by the patient's attendants and by flies.

On collieries all preventive measures are carried out by the colliery medical staffs under the supervision of the circle staff of the Mines Board of Health.

With regard to treatment, cases of cholera occurring on collieries are treated by the colliery doctor babus, and by far the greater proportion of cases occurring in the villages of the settlement also receive treatment for payment by the same agency. A certain proportion of the cases, however, formerly, either through poverty or from remoteness from medical aid, received no treatment, and as the mortality rate in such untreated cases was found year after year to be in the neighbourhood of 90 per cent., it seemed to the writer that it was the duty of the Mines Board of Health on humanitarian grounds to undertake the treatment of all such cases.

The selection of a remedy then presented itself for solution, the remedy to be adopted having to fulfil certain conditions, viz., it had to be cheap, speedy and certain in action, and non-poisonous, since it was intended to be administered by the subordinate outdoor staff of the board, who possess no medical knowledge or qualifications.

For the treatment of cholera at the time the only recognized medical remedies were chlorodyne, kaolin and potassium permanganate pills. Of these chlorodyne was at once rejected as being a scheduled poison, kaoline after trial was rejected as being unpopular and unsuitable for field work on account of its bulk, though the results obtained in cases which persevered with the treatment were very satisfactory, showing a mortality rate of only 25 per cent.; potassium permanganate pills on trial were rejected as valueless.

Some years prior to becoming the health officer of the Mines Board the writer's attention was drawn to a formula formerly widely used throughout India and known variously as "mist. pro-diarrhœa" or "cholera drops," which, for some reason or other, had fallen into desuetude, probably owing partly to the fondness of the profession for new remedies and partly to failure to administer the mixture in effective doses. The actual formula was a somewhat complicated one, but was in reality a solution of the oils of aniseed, juniper and cajaput in alcohol and ether, acidified with one per cent. sulphuric acid. This solution, so far as the writer was able to ascertain, had commonly been administered in *drops*, the number and frequency of administration of which being left to the discretion of each individual prescriber. On theoretical grounds the formula seemed to the writer to be likely to prove an excellent one if administered rapidly in sufficient doses, the alcohol and ether forming jointly a highly diffusible stimulant, while the essential oils are both germicidal and carminative, oil of juniper being at the same time a potent diuretic.

The writer, therefore, advised the Mines Board to adopt the formula in the form given below:—

		Minims.
℞.	Ol. anisi (or cloves)	5
	Ol. cajaput	5
	Ol. juniper	5
	Acid. sulph. aromat	15
	Spt. æther	30

Misce.—1 dram every half-hour or ½ dram every quarter hour in water until 1 ounce has been given and thereafter 1 dram every hour until complete recovery has taken place.

(The mixture can conveniently be made up in bulk by mixing 1 lb. of each of the oils named, with 3 lb. of acid. sulph. aromat. and 6 lb. of spt. æther, the oils being added last to ensure their ready solution.)

Oil of cloves was at first substituted for the oil of aniseed in the original formula on the assumption that it would be more highly germicidal and that better results would therefore be secured. Experience, meanwhile, in Madras and in the mining settlement has proved that oil of cloves possesses no marked superiority over oil of aniseed and that the latter produces a much less pungent and more palatable mixture; oil of aniseed has, therefore, now been permanently adopted in place of oil of cloves.

On trial this mixture proved of the greatest value, as vomiting and purging were found to cease almost immediately after its administration, collapse being thus obviated in practically every instance. From the records of hundreds of cases treated with the mixture in the mining settlement during the past three years it can be confidently stated that if administered according to directions before collapse has set in the mixture is capable of curing 95 per cent. of cases, intravenous isotonic saline injections alone or combined with alkalies in the form of sodium bicarbonate, 160 gr. to the pint, as recommended by Sellands, being necessary in those cases only in which for any reason collapse ensues. Shortly after the introduction of the essential oils mixture an outbreak of cholera was reported from a village in the

settlement where the inhabitants of a whole line of huts had drunk the water of a cholera-infected tank, many persons being struck down with the disease simultaneously. These cases all accepted the offer of treatment by the board's staff with the essential oils mixture, and while the staff were carrying this treatment out several fresh cases were observed to develop.

These latter cases also were forthwith treated with the mixture and it was found that vomiting and purging thereupon immediately ceased, the disease apparently being aborted in every instance. On this being verified by the writer it seemed to him that if the mixture was able to abort the disease at its incipient stage it ought also to be able to prevent the onset of symptoms in those exposed to infection by contact, if administered in sufficient doses in due time. Accordingly, orders were issued to the staff that in future in all instances, whether the patient was being treated with the essential oils mixture by the board's outdoor staff or not, all contacts living in houses where cholera existed were to have the mixture administered to them at least once a day as a prophylactic, those actually engaged in nursing to receive the mixture both morning and evening. The results of this procedure have far exceeded all expectations, for amongst some thousands of house contacts in the mining settlement thus treated with the mixture as a prophylactic during the past three years less than 1 per cent. have subsequently developed the disease. In those cases, moreover, in which the disease actually develops, in spite of the generally effective prophylactic doses, it is observed that the symptoms are mild and readily respond to further treatment with the essential oils mixture. From investigations at present being carried out there is reason to believe that almost *absolute* protection for the individual can be obtained by administration of the mixture as a prophylactic three times a day. In the *Indian Medical Gazette* of April, 1925, p. 155, a suggestion was put forward by a writer that the good effects of the essential oils mixture, both in treatment and prophylaxis, were probably due to the aromatic sulphuric acid which it contains. Experiments since carried out in the mining settlement have shown that this is not the case, aromatic sulphuric acid being practically valueless as a prophylactic, though of considerable value in treatment if given in full doses with the same frequency as the essential oils mixture. As a treatment, aromatic sulphuric acid would appear to be of about the same value as the common "cholera mixture" containing opium in some form or other, the mortality rate from treatment with which in the mining settlement has been found in hundreds of cases over a long series of years to be consistently in the neighbourhood of 50 per cent., as compared with a mortality rate of 90 per cent. in untreated cases.

The great value of the essential oils mixture in cholera may be summed up as follows:—

(1) If administered as soon as vomiting and purging declare themselves it immediately aborts the disease and prevents the onset of collapse.

(2) It is a valuable and highly efficient prophylactic.

(3) Its administration can be entrusted to any intelligent layman.

(4) One person can attend to hundreds of cases if necessary at one and the same time.

(5) It is cheap, palatable and non-poisonous.

Abnormal Bacteria Flagella in Cultures (H. Noguchi, *Journal of the American Medical Association*, May 1, 1926).—These investigations show that besides the leptospira-like filaments, probably originating from red blood-corpuscles under certain conditions *in vitro*, other spiral elements exist which may be erroneously interpreted as spirochætes. These are the exaggerated detached flagella of certain bacteria, produced under cultural conditions. In cultural studies of micro-organisms the occurrence of these spiral elements must be borne in mind, particularly in connection with dark field illumination. Spirochætes belonging to the *Spironema* and *Treponema* groups also produce, under certain cultural conditions, exaggerated flagellar appendages. These terminal flagella are similar in appearance and structure to the axial spiral filaments of the same organisms, but are much finer. The axial filaments are covered with a layer of cytoplasm which can be removed by the action of bile. The motility of these organisms resides in the portion of the filament next the attachment of the flagellum at either end. The great resemblance which exists between the flagella of motile bacteria and the flagellar and axial spiral apparatus of certain spirochætes seems to indicate that the axial filaments are probably a modified apparatus of similar origin, especially adapted to the locomotion of spirochætes, and therefore supports the hypothesis of a close phylogenic relationship between bacteria and spirochætes.

Identity of Ohara's Disease and Tularæmia (F. Francis and D. Moore, *Journal of the American Medical Association*, May 1, 1926).—Ohara's description of the clinical and epidemiological characteristics of a disease observed in Fukushima city, Japan, agrees even in minor details with the picture of tularæmia. The following tests were made in Washington, D.C., by the United States Public Health Service: (1) Serums collected and forwarded by Ohara from cases which came under his observation were agglutinated and *Bacterium tularense* was isolated: (2) Reciprocal agglutination absorption tests failed to distinguish any difference between the Japanese culture and an American culture. The conclusion reached is that Ohara's disease occurring in Japan and tularæmia occurring in the United States are identical.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—**All literary communications should be addressed to the Editors.**

4.—**All business communications and payments, either of** subscriptions or advertisements, **should be sent to the Publishers of** THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—**The Subscription, which is Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—**Authors desiring additional reprints of their communications to** THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE **should communicate with the Publishers.**

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

Tropical Medicine and Hygiene

JULY 15, 1926.

GANGRENE IN MALARIA.

AMONGST the complications and sequelæ of the infectious diseases gangrene, usually occurring as a symmetrical gangrene of the extremities, constitutes one of the most rarely encountered phenomena, and one that is barely mentioned in the textbooks.

In 1904, however, Barraud collected and analysed a series of 103 cases of gangrene of the extremities following the various infectious diseases. He limited his investigations to cases occurring in young persons, thus eliminating cases of senile or pre-senile gangrene due to arterio-sclerosis in older subjects; he also excluded cases of spontaneous gangrene resulting from Raynaud's disease.

In this series of 103 cases the gangrene had resulted from typhoid fever in 44 cases, from typhus fever in 11, from measles in 6, from scarlet fever, pneumonia and acute articular rheumatism in 5 each, from influenza, diphtheria, erysipelas and malaria in 2 each, from pertussis, dysentery, relapsing fever, and cholera morbus in 1 each, and from various surgical conditions in 14. The small number contributed to this list by malaria indicates the variety of the occurrence of gangrene in malaria and it would appear that of all the complications and sequelæ of malaria gangrene constitutes one of the most rarely encountered.

Nevertheless, this condition had been recorded even before Laveran had announced the discovery of the pathogenic agent of malaria, for in 1869 Rey reported the first case of symmetrical gangrene in a man who had suffered from intermittent fever in Senegal and had had a relapse on his return to France. Laveran himself also described a case of gangrene of both lower extremities as a complication of malaria. Further cases were recorded, 1 by Osler in 1900, 2 from India by Hammond in 1913, and 2 by Paisseau and Lemaire in 1917.

In Osler's case the gangrene involved the feet, hands, buttocks and occiput, and the blood contained crescents and æstivo-autumnal organisms in unusually large numbers. In Hammond's cases the extremities were also affected, one case recovering, the other being fatal. In the case which recovered malignant tertian rings were abundantly present, but in the fatal case the type of malaria is not mentioned.

In Paisseau and Lemaire's 2 cases the gangrene was symmetrical and involved the lower extremities. Both were fatal, and both showed a severe infection with *Plasmodium falciparum*.

Slaughter (*Journal American Medical Association*, May 22, 1926) has recently reported a further case in which a young American seaman contracted malaria in San Domingo after being shipwrecked off Haiti. The infection was æstivo-autumnal malaria of the delirious pernicious type, with acute nephritis and hæmoglobinuria; and the gangrene was symmetrical in both feet, necessitating amputation of the right great toe at the metatarso-phalangeal articulation.

He responded well to intravenous medication with quinine, and three months after admission was discharged from hospital in good physical condition. The feet had completely recovered except for a tingling sensation on walking.

The differential diagnosis of this case, as worked

out by Slaughter, presents several points of interest.

The absence of pulsation in the dorsalis pedis artery eliminated a symmetrical gangrene of the Raynaud type due to vaso-constriction. The absence of pulsation pointed to embolism or thrombosis, and thrombosis appeared to be the most probable causative factor. As there was no evidence of heart disease, the gangrene was not due to embolism associated with heart disease. Trauma, heat, cold, chemicals and drugs were all readily excluded as the cause of the gangrene.

Syphilis was eliminated as the cause of the gangrene, as there was neither history nor evidence of syphilis, and the Wassermann reaction was repeatedly negative.

Diabetic gangrene was eliminated on laboratory findings.

Senile gangrene was eliminated by the patient's age, by the physical examination and by the symmetry of the lesions.

Thrombo-angiitis obliterans was eliminated by the absence of redness, intermittent claudication and migrating phlebitis, and by the history and course of the case.

The polyneuritis of beriberi, erythromelalgia and syringomyelia were all considered and eliminated as the cause of the gangrene.

With regard to the manner in which the gangrene is brought about by malarial infection it is agreed that gangrene is the result of lack of nourishment of the part affected, due to arterial obstruction, and is therefore usually encountered as the dry type of gangrene.

The arterial obstruction may result from three factors, namely, constriction of the arterioles, due to spasm or vaso-constriction, embolism or thrombosis. The trend of present-day opinion appears to favour the view that thrombosis is the usual causative factor.

It is further to be noted that in the recorded cases in which the type of malaria is mentioned, it is always the malignant tertian type of malaria in which gangrene of the extremities occurs, that the infection is of a very severe character, having a high mortality, and that the most favourable results are to be expected from the energetic application of quinine by intravenous medication.

F. E. T.

Annotations.

Angioneurotic Œdema. Report of Case with Necropsy Findings. (I. M. Wason, *Journal of the American Medical Association*, May 1, 1926).—Watson describes a condition of extreme œdema of the respiratory tract, with mild and variable type of cellular reaction. In some sections of the lungs the character of the response suggests an early inflammation. In other sections of the lungs and the pharynx the picture is not unlike that sometimes seen following protein sensitization; namely, a predominance of mononuclear cells.

Use of Iodized Oil in Diagnosis and Treatment of Bronchial Affections (S. Pritchard, B. White and J. K. M. Gordon, *Journal of the American Medical Association*, May 1, 1926).—By the injections of iodized oil into the bronchial tree, small bronchiectatic dilatations in and around the roots of the lungs and cylindric fusiform enlargements of the descending branches may be revealed in many cases of chronic cough, which a previous exhaustive examination of the chest failed to show. The entire bronchial tree cannot be visualized at one injection. Small sections should be injected at intervals until any abnormality is discovered or the entire field is studied. The nose and throat should be studied in all cases. Bronchiectatic cavities occur as the result of chronic upper respiratory infections and may continue to cause cough after the tonsils are removed or the sinuses drained. In the majority of cases, the supraglottic method of injecting the lung-roots and descending branches of the bronchial tree takes less time, less anæsthesia, is less worry for the patients and gives results quite as satisfactory as other methods. It is not necessary to use extensive local anæsthesia in the majority of cases. In more than 600 bronchial injections of iodized oil, no ill-effects occurred. The technique is not difficult. It requires no special training. Negative results of an injection are no diagnostic proof that bronchiectatic dilatations do not exist. The therapeutic use of iodine is not new, but this compound of iodized oil is a new combination, and, as a result of the slow liberation of the iodine in the bronchial tree, acts as an ideal treatment in chronic affections of the lower respiratory tract. In acute affections or pulmonary tuberculosis, iodized oil for either diagnostic or therapeutic purposes should not be used.

Exophthalmic Goitre. A Follow-up Study of Cases Treated with the Roentgen-Ray (B. J. Sanger, *Archives of Internal Medicine*, May 15, 1926).—Fifty patients with exophthalmic goitre were carefully studied under Roentgen-ray therapy. They were followed at frequent intervals during their course of treatment and subsequent to their recovery with basal metabolism and clinical observations. Some have been followed for as long as five years. The great majority, 82 per cent., became well and remained so. Of the remaining 18 per cent., 6 per cent. were improved, 8 per cent. were operated on, and 4 per cent. were lost to the follow-up clinic during last year, so that the ultimate result is doubtful. On the whole, the Roentgen-ray offers a safe and satisfactory therapeutic procedure with a high percentage of cures, in cases of exophthalmic goitre.

Iodized Salt in the Prevention of Goitre. Is it a Safe Measure for General Use? (C. L. Hartsock, *Journal of the American Medical Association*,

May 1, 1926).—Iodine administered in small quantities, periodically, to children under the age of puberty is a very efficient preventive of simple goitre. Its use should be begun early and continued until puberty. At the age of puberty before iodine is prescribed a careful examination of the thyroid gland should be made by a physician to determine whether or not fœtal adenomas are present; if iodine is used at all, it should be used with great caution, and in all cases the patient should be warned to discontinue the iodine should symptoms of hyperthyroidism occur. The continuous use of iodine over a long period of time should never be prescribed for adults, and when its periodic use is prescribed, frequent observations of the pulse and weight should be made. Under no circumstances should iodine be administered to adults with fœtal adenomas, either with or without symptoms of hyperthyroidism, except for a short period preceding operation. In the occasional case in which there is temporary improvement, the patient will be lulled to false security and eventually a marked overactivity of the gland will result if the use of iodine is continued. In the case of an adult patient who has a simple, large colloid goitre or a large colloid adenomatous goitre without fœtal adenoma, iodine sometimes has remarkably beneficial results and may be tried, but only with extreme caution, as it is this type of goitre that may become suddenly and overwhelmingly active, so that what appears one week to be a wonderful clinical result in every way may be a fulminating case of hyperthyroidism the next week, with a basal metabolic rate of plus 75 to 100, marked asthenia and a loss of from 5 lb. to 10 lb. (2 to 4 kg.) in one week. If compound solution of iodine or iodine is administered in cases of exophthalmic goitre in which operation is not to be done, it should be discontinued or very greatly reduced when the basal metabolic rate is lowered and clinical symptoms improve. Continued use of the iodine will often again overactivate the thyroid gland. Iodine should not be administered to a patient who has recovered after thyroidectomy unless hyperthyroidism exists, and even in these cases thyroid extract is usually more satisfactory. Iodine is most efficiently administered and controlled in the form of chocolate tablets containing 10 mg. of organic iodine, or compound solution of iodine (Lugol's solution) when this is given under medical supervision. Periodic administration of iodine is always preferable. Iodine may be administered in small doses to the pregnant woman for the prevention of goitre in the fœtus. It is supposed to prevent fœtal adenoma as well as colloid goitre. The amount of iodine required for this purpose is exceedingly small, and the best form in which to administer it is the chocolate tablet. Extreme caution must be used as the thyroid gland is in a very unstable condition during pregnancy and iodine may cause it to become hyperactive. When overactivity of a thyroid gland has been induced by iodine, it usually does not subside when the iodine is discontinued, just as hyperactivity of the gland due to any other cause may not subside with the withdrawal of the exciting agent. In either case an operation is usually required. The author states that this article is in no way a criticism of the principle of goitre prevention as a whole, for in this field lie untold possibilities for the future. The criticism is directed solely against the fallacious ideas regarding the use of iodine which have gained such wide publicity. Community administration of iodine disregards physiologic facts regarding the effect of iodine on the thyroid gland. The use of iodized salt, in particular, should be discontinued or limited absolutely to periodic table use by children under the age of puberty.

Urinary Proteins. Crystalline Proteins of Nephritis (W. H. Walker, W. A. Thomas and L. Hecktoen, *Journal of the American Medical Association*, May 1, 1926).—In ten cases of nephritis, proteins were obtained in the form of globular crystals from the urine. In one instance the protein appeared as needle-like crystals. Precipitin tests indicate that the protein crystals consist of compounds of serum albumin, euglobulin and pseudoglobulin.

The Mode of Action of Bayer "205" on Trypanosomes (I. J. Kligler and I. Weitzman, *Annals of Tropical Medicine and Parasitology*, July 26, 1925).—The experiments described have brought about two interesting facts. First that contrary to the general belief that Bayer 205 exerts little trypanocidal action *in vitro*, it appears that the drug has a marked effect on the cell so that a dilution of 1:1,600 is sufficient to destroy the virulence of the organisms. Second, that in rabbits at least, the therapeutic, abortive and prophylactic doses are similar. A dose of 0·1 grm. per kilo cured all animals; 0·05 grm. per kilo gave about 80 per cent. cures, while 0·005 grm. per kilo was not effective. The therapeutic property of Bayer 205 is due to a direct injury to the trypanosomes which renders them avirulent for the host and thus readily destroyed and eliminated.

A Case of Sickle-cell Anæmia in the Sudan (R. G. Archibald, *Transactions of the Royal Society of Tropical Medicine and Hygiene*, January 21, 1926).—A case of anæmia associated with marked debility, pyrexia, slight jaundice, œdema of the feet, enlargement of the liver and lymphatic glands, occurring in a native of the Sudan is described. Blood examination showed a diminution of the red blood-cells, leucocytosis, low hæmoglobin percentage, colour index of 0·9, erythroblasts and phagocytosis of red blood-cells. The most striking feature in fresh and stained preparations of the blood was the large number of elongated and sickle-shaped erythrocytes, averaging nearly 50 per cent. Hanging-drop

preparations of fresh blood suitably sealed and kept at room temperature (31° C) showed, after twenty-four hours, nearly 100 per cent. of sickle cells. The sickling is apparently due to some inherent property of the cell, independent of any substance in the serum. The blood picture is identical with that of sickle-cell anæmia, differing only in the absence of any skin lesion. The ætiology is obscure, cultural tests and animal inoculations yielding negative results.

A New Method of Diagnosis and of Vaccine Treatment in Leprosy (J. Hasson, *Transactions of the Royal Society of Tropical Medicine and Hygiene*, January 21, 1926).—The author claims to have proved the success of vaccine treatment in leprosy and remarks that in future, if anti-leprosy therapy is to succeed, the physician must resort to vaccine therapy and leave the other preparations, the so-called "specifics" in leprosy for the treatment of consolidation. Chaulmoogra, in its various forms, is to be rejected in the treatment of "attack" conditions, since it cannot be relied upon to give the desired results. The author will be glad to supply small quantities of vaccine to anyone desiring to test the claims made.

A Contribution to the Study of Onchocerca volvulus Leuckart, with some Observations on its Prevalence in Nigeria (N. A. Dyce Sharp, *Transactions of the Royal Society of Tropical Medicine and Hygiene*, January 21, 1926).—Onchocerciasis is not confined to persons exhibiting obvious tumours or skin affections, and is, moreover, far more common than has hitherto been described. Parsons, of Nigeria, anticipated this in 1911. The embryosis is more often found in the skin than in definite tumours. The larvæ of *O. volvulus* occur with great frequency in hydrocele fluid in Nigeria, and, while possibly innocuous, they may well stand in some causal relationship to this condition as well as to elephantiasis. *Agamofilaria streptocerca* Macfie and Corson, 1922, is not found at Kaduna among natives drawn from all over the country. This organism, moreover, is easily distinguishable from the embryos of *O. volvulus*, with which on the Gold Coast it is so often associated.

Treatment of Leprosy by a Vaccine of Autolysed Tubercle Bacilli (R. Row, *Transactions of the Royal Society of Tropical Medicine and Hygiene*, January 21, 1926).—Since sera from leprous patients show a very strong antibody content against the antigens contained in the author's autolysed tubercle vaccine, an attempt was made to extend the application of this vaccine to nerve and nodular leprosy. The following results have been obtained by a prolonged course of weekly injections of 0·025 mg. of the autolysed tubercle material lasting five months or more. Thickened nerve trunks became smaller and assumed normal size. Anæsthetic areas lost their anæsthesia, became glossy at first and resumed practically normal conditions with the growth of hair where this was lost. The margins of these areas became flush with the surrounding skin and beyond a slight discoloration nothing abnormal can now be noticed in them. Trophic and perforating ulcers heal rapidly, but in some cases the vulnerability of the parts remains, even after healing of the ulcer. Atrophied muscles, if recovering at all, are very slow in doing so; they remain atrophied when the disease has destroyed muscular tissue. In disfigured conditions of the face the vaccine seems to be of benefit in restoring the natural contour of the features, the thickening of the parts gradually disappearing. In defined nodular lesions the prolonged course of the vaccine leads to their complete absorption and to the return of the features to normal. In all cases this autolysed tubercle vaccine has been administered subcutaneously every week without exciting any local, focal, or general reaction. The first three or four injections usually do not produce any change in the lesions, but may sometimes make them appear a little angry.

Medical News

At the Annual Meeting of the Royal Society of Tropical Medicine and Hygiene, held at 11, Chandos Street, London, on Thursday, June 17, the Manson Medal was presented to Senator Professor Ettore Marchiafava, of Rome, in recognition of the part he took in the elucidation of the life-history of the parasites of human malaria.

The foundation stone of the new house of the London School of Hygiene and Tropical Medicine, the gift of the Rockefeller Foundation, was laid at 3.30 p.m. on Wednesday, July 7, by Mr. Neville Chamberlain, Minister of Health.

The Ross Institute and Hospital for Tropical Diseases, Putney Heath, London, S.W.15, will be opened by H.R.H. The Prince of Wales to-day, Thursday, July 15.

THE UNIVERSITY OF LIVERPOOL.

EXAMINATION LIST.

June, 1926.

Faculty of Medicine—Diploma in Tropical Hygiene.

Original Communication.

OBSERVATIONS ON THE IMPORTANCE OF SYMBIOSIS OR CLOSE ASSOCIATION OF DIFFERENT SPECIES OF ORGANISMS IN THE PRODUCTION OF CERTAIN BIOCHEMICAL PHENOMENA AND IN THE CAUSATION OF CERTAIN DISEASES AND CERTAIN SYMPTOMS OF DISEASE.

By Aldo Castellani, C.M.G., M.D., F.R.C.P.

The subject of symbiosis has, so far, attracted little attention from medical men and bacteriologists. I use the term symbiosis *sensu lato* to indicate the living together of two organisms in close association, their close association not being detrimental to either of them; symbiosis *sensu stricto* means that the association is not only not detrimental, but mutually beneficial. Botanists, on the other hand, have been interested in symbiosis for many years. They discovered, for instance, that a large group of plants represents a symbiosis of two different vegetal organisms; they also found that symbiosis plays an important rôle in the nutrition process of numerous plants and in the germination of certain seeds.

Symbiosis between two vegetal organisms. Composite plants.—The best known example is furnished by the lichens. A lichen is a composite plant consisting of a green alga and a fungus which may be grown separately with difficulty. All of us have observed the green dust which often occurs on lichens. This powdery dust consists of young associations called soredia of algal cells and fungal hyphæ. Another well-known symbiotic plant is the ginger-beer plant, the lumps of which are composed of a yeast (*Saccharomyces pyriformis*) and a bacterium (*Bacterium vermiforme*).

Symbiosis between a vegetal organism and an animal organism.—Symbiosis may also occur between plant and animal. For instance, in the marine worm convoluta an alga is always present, and in the larvæ of certain aphids, coccids, &c., yeasts occur as more or less definite structures.

Importance of symbiosis in the nutrition process of certain plants.—Reissek, in 1847, came to the conclusion that fungi were normally present within the cortical cells of the roots of various flowering plants, being best developed in the underground roots of orchids. Soon after, another type of association was noted, especially in forest trees. Here the fungus mycelium forms a sort of mantle around the root, in contrast to being within the cells of the cortex. This association is very common in *Castanea* and *Corylus*. The rootlets so infected generally take a characteristic coralloid appearance. Frank, in 1885, coined the term " mycorrhiza " to denote fungi (including bacteria) in or around the roots of plants. He used the term " endotrophic mycorrhiza " for those forms in which the fungus occurred within the tissues of the host, and the term " ectotrophic mycorrhiza " when the fungal mycelium surrounded the rootlets as a sheath.

The antiquity of such associations is seen in the fact that they occur in fossil plants such as *Rhynia*, *Hornea*, and *Asteroxylon* from the Lower (or Middle) Devonian. Weiss, in 1906, recorded mycorrhiza in fossil roots from the lower coal measures, for which he suggested the name " mycorrhizonium."

A well-known instance of symbiosis is represented by the nodules found in the roots of many leguminous plants. For many years it was noted that roots of leguminous plants such as peas and clover presented a large number of nodules or tubercles which were for a long time considered to be normal morphological features of such plants. Later it was

Fig. 1.

found that these nodules are formed by the presence of a bacillus (*B. radicola*). This bacillus is apparently always present in the soil; the bacillus enters through a root-hair, it reaches the interior of the cortex and begins multiplying there, producing the nodular outgrowths. The organism feeds and grows principally on the carbohydrates (sugars, &c.) supplied by the host plant, these having been produced as the result of the photosynthetic activity of plant leaves. The bacillus is therefore supplied by the plant with carbohydrate food, but the bacillus in return supplies the plant with the nitrogenous compounds necessary for the production of protoplasm, by utilizing the *free nitrogen* of the air circulating in the soil.

Most plants have to take their nitrogen in a combined form, as ammonia salts, nitrates, &c., as nitrogen is a very inert element and difficult to force into combination with others. *B. radicola* is one of the very few organisms which can perform this really stupendous work, provided that it is supplied with the means of obtaining the energy required for

the process in the form of appropriate carbohydrate nutrition. There cannot be any doubt about the facts, for the bacillus will do the same thing when cultivated outside the plant under strict experimental conditions.

After the bacilli have thriven for a while, mainly at the expense of the food supplied by the root in which they are living and multiplying, many of the individuals become weaker and undergo a sort of degeneration, whilst a few pass into a resting stage, in which they become highly resistent to adverse conditions of life. The leguminous plant, which hitherto has been giving out carbohydrate food to the bacillus, now begins to receive: it receives from the degenerated mass of bacilli the stores of nitrogenous matter they have accumulated, and this is a very good return for the sugars which it had previously expended. The comparatively few surviving bacilli serve to infect the soil—as the roots gradually rot—and then they are enabled to attack the roots of new leguminous plants.

Higher Plants.—The phenomena of symbiosis between root and fungi occur also in many plants higher than the leguminous, for instance in forest trees. In these trees the fungus mycelium forms a sort of mantle round the root, in contrast to being inside the cells of the cortex. The association is very common in *Castanea* and *Corylus*, the rootlets so infected generally taking a characteristic coralloid appearance.

Importance of Symbiosis in the Phenomena of Reproduction. Germination of Seeds.—Noel Bernard, in 1902, proved experimentally that certain seeds, as the seeds of orchids, can germinate only in the presence of appropriate fungi. If the seedling is not infected with the appropriate fungus, generally the same fungus which infects the roots of the adult parent plant, as a rule germination will not take place, or it will be slow and imperfect. Burgeff came to the same conclusion, viz., that orchid seeds germinate without difficulty on having the appropriate fungus supplied to them. It is interesting to note that before this was scientifically known, orchid growers had found that to make orchid seeds grow it was necessary to sow them in the soil containing the parent plant; the explanation is that the seed in this way got infected with the fungi necessary to induce germination, viz., the fungus which is found in the roots of orchids.

A few more details may be of interest: Orchid seeds taken from the capsule under sterile conditions and sown on ordinary substrata where no fungus is present do not as a rule develop. The only phenomenon observed in these conditions is that usually the seeds swell and after two or three months—viz., after the reserve food, which is oil, part of which becomes transformed into starch, has been exhausted—become green and soon after die, unless the fungus infestation takes place. At first it seems peculiar that the seeds should die after the production of chlorophyle; one would rather expect that autonomous growth by action of photo-synthesis should take place; as T. Ramsbottom aptly put it, it appears that the seedling forms chlorophyle as a sort of a last despairing effort.

Importance of Symbiosis in Fermentation Phenomena.—Two organisms neither of which alone produces gas-fermentation in certain carbohydrates may do so when living in symbiosis or artificially mixed together. This phenomenon is sometimes referred to as Castellani's phenomenon.

During the years 1904 and 1905, while in the East and in London on leave, I became interested in the study of baker's yeast and in fermentation caused by yeast. I made the following observations, mentioned at meetings of the Ceylon Branch of the British Medical Association.

(1) Baker's yeast, both in the East and in London, is not a pure culture of a single species of yeast. It is generally composed of two or more species of yeast plus one or two or several species of bacteria. The bacteria isolated from samples of yeast in the East and in London do not produce gas-fermentation in sugars—they produce simple acidity.

(2) Comparing the fermentation reactions of baker's yeast used *in toto* as obtained from the bakers, sowing the particles of the sample in the various sugars, with the fermentation reactions of the isolated pure cultures of the different species of saccharomyces and bacteria composing the sample, I found that the yeast *in toto* often ferments a larger number of carbohydrates than any one of the saccharomyces and bacteria composing the sample.

(3) By mixing artificially all the organisms isolated from the sample of yeast, in certain cases the same fermentation reactions are obtained as with the yeast *in toto*. There are apparent exceptions, as shown by the following example. From Orpington, a place in the country near London, I obtained in 1919 a sample of baker's yeast which gas-fermented a very large number of carbon compounds, including starch. I investigated the sample mycologically by plating on maltose and glucose agar, &c., and I isolated and grew in pure cultures all the organisms, saccharomyces and bacteria, apparently present in that sample. By mixing all the pure cultures, I obtained the same fermentation reactions as with the sample of yeast *in toto*, except that the mixture did not ferment starch. The experiment was repeated many times with the same result, until finally I had recourse to the following procedure: the surface of the glucose agar plates on which a minute particle of the yeast-cake had been plated out was washed with a little peptone water and the washing inoculated into starch. Fermentation took place, the inference being that probably some very minute colonies on the verge of invisibility had escaped my notice when investigating the plates and picking out all the colonies present; the thought came to me also that there might be an ultramicroscopic germ present.

(4) By mixing artificially a non-maltose fermenting saccharomyces (isolated from a sample of baker's yeast) with a bacillus isolated from the same sample, producing acidity in maltose and several other sugars, but never gas in any substance, I obtained fermentation of maltose with production of gas.

(5) In Ceylon by mixing two saccharomyces

isolated locally, neither of which alone produced gas or acidity in maltose, gas-fermentation of that sugar was obtained.

In recent years I have studied the same and similar phenomena, using mostly pathogenic bacteria: bacilli and cocci, also a pathogenic yeast. In the present paper I will limit myself to giving the results of experiments—a number of them already published—with the following organisms:—

(*a*) *Bacilli.*—*B. typhosus*, *B. dysenteriæ* Flexner, *B. morgani*, *B. proteus*, strain P., *B. coli communior*, *B. kandiensis*, *B. vermiculoides*.

(*b*) *Cocci.*—*Staphylococcus aureus*, two strains of *Streptococcus pyogenes*.

(*c*) *Yeast.*—*Cryptococcus graciloides*.

The strain of *B. typhosus* was isolated from a case of typhoid fever and shows all the typical serological reactions and biochemical characteristics of the typhoid bacillus; it is very highly agglutinated by typhoid serum; it does not produce gas in any carbohydrate; it produces acidity in glucose, levulose, maltose, galactose, mannitol, dextrin, and sorbite.

The strain of *B. morgani* was isolated from a stool; it is motile; it produces acidity and gas in glucose, levulose, and galactose, but neither acidity nor gas in any other sugar. In this paper I will refer to it as Strain S.

The strain of *B. dysenteriæ* Flexner is serologically and biochemically typical; it produces acidity in mannitol. It was obtained from the Lister Institute.

The strain of *B. proteus* was isolated from a case of enteritis; it is motile and liquefies gelatine and serum rapidly; it produces acidity and gas in glucose, levulose, galactose, saccharose, and glycerol; it produces neither acidity nor gas in lactose, dulcitol, mannitol, maltose, dextrin, adonite, inulin, sorbite, inosite, salicin, amygdalin, isodulcitol, or erythrite. As I have stated in other publications, the term *proteus* covers a group of closely allied bacilli and not one species only. The strain I have used is very similar to the variety which I called *paradiffluens* (see Castellani and Chalmers' "Manual of Tropical Medicine," 3rd edition, page 943). In this paper I will denote it as *B. proteus* (P).

B. kandiensis is an intestinal bacillus somewhat related to *B. typhosus*: it is motile and does not produce gas in any sugar; it produces acidity in glucose, levulose, galactose, mannitol, adonite, inosite, isodulcitol, erythrite; it does not clot milk; does not produce indol. There is a variety producing indol (*kandiensoides*).

The strain of *B. coli communior* produces gas in many sugars, including saccharose, but does not produce either acidity or gas in adonite.

The strain of *Staphylococcus aureus* was isolated at the Ross Institute, London.

The two strains of *Streptococcus pyogenes* were obtained from the Laboratories of Public Health, London.

B. vermiculoides and *Cryptococcus graciloides* were isolated from two cases of stomatitis cryptococco-bacillaris in Central America.

B. TYPHOSUS + B. MORGANI.

Action on Maltose.—*B. typhosus* alone produces acidity, never gas. *B. morgani* alone has no action whatever on maltose; it produces neither acidity nor gas. If a tube of maltose peptone water is inoculated, however, with *B. typhosus* and immediately after with *B. morgani* and placed in the incubator at 35° C. or 37° C. for 48 hours, not only will acidity be produced, but also a large amount of gas. The same result is obtained if the two bacilli are previously mixed in plain peptone water and the peptone water mixture inoculated into tubes of maltose. The same result is also obtained if *B. morgani* is added to *B. typhosus* twenty-four hours after inoculating with *B. typhosus;* if the interval is more than twenty-four hours, then the production of gas is not so constant.

When the two bacilli, *B. typhosus* and *B. morgani*, live naturally in close association, the same phenomenon takes place, as shown by the following observation, which I related in one of my previous papers: The stool of a suspected typhoid case was examined bacteriologically in London, using MacConkey's medium plates. An exceptionally large number of white colonies developed; fifteen were picked out and investigated further by replating, &c. Twelve of them consisted of two organisms—*B. typhosus* and *B. morgani:* three of *B. morgani* alone. The cultures derived from the colonies containing *B. morgani* only, had no action whatever on that sugar. Mixed cultures obtained artificially by inoculating agar tubes with both *B. typhosus* and *B. morgani* behave in the same manner—namely, when a loopful of the mixed growth is inoculated into a maltose peptone water tube, acid and gas are produced.

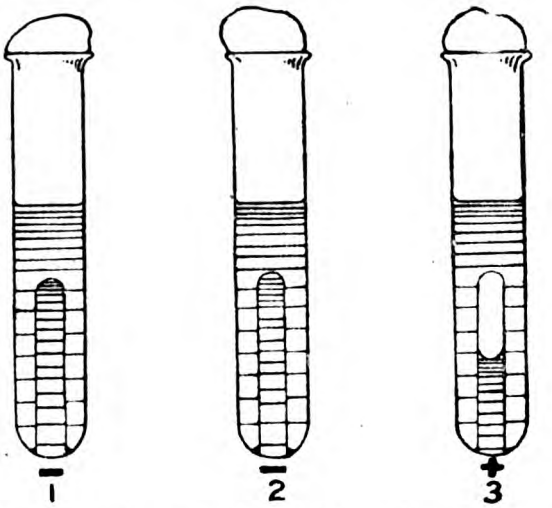

FIG. 2.—Action on maltose of *B. typhosus* alone, gas absent (1), *B. morgani* alone, gas absent (2), and *B. typhosus* + *B. morgani*, gas present (3).

Action on Mannitol.—As is well known, *B. typhosus* produces acidity only in mannitol, never gas; *B. morgani* has no action—no acidity or gas is

produced. The mixture *B. typhosus* + *B. morgani* produces acidity and gas.

Action on Sorbite.—*B. typhosus* alone produces acidity, never gas, in sorbite; *B. morgani* alone has no action whatever on sorbite; it produces neither acidity nor gas. The mixture *B. typhosus* + *B. morgani* produces acidity and gas.

Action on other Carbon Compounds apart from the above.—The reactions are seen at a glance in Table I, in which the fermentative characters are given of *B. typhosus* alone, *B. morgani* alone, and the mixture of *B. typhosus* + *B. morgani*.

TABLE I.

	Lactose	Saccharose	Glucose	Levulose	Maltose	Galactose	Mannitol	Sorbite
B. typhosus	O	O	A	A	A	A	A	A
B. morgani	O	O	AG	AG	O	AG	O	O
B. typhosus + *B. morgani*	O	O	AG	AG	AG	AG	AG	AG

O = negative, neither acid nor gas; A = acid; G = gas.

From the table it is seen that certain sugars and other carbon compounds, which when acted upon by *B. typhosus* alone undergo a simple acid fermentation, and when acted upon by *B. morgani* alone do not undergo any fermentation, neither acid nor gas being produced, they are capable of undergoing fermentation with production of gas when they are acted upon by the mixture of the two bacilli. In the carbon compounds in which *B. typhosus* alone produces no acidity and *B. morgani* alone neither acidity nor gas, their mixture produces neither acidity nor gas.

B. TYPHOSUS + B. PROTEUS.

The strain of *B. proteus* used (P), as already stated, has no action on maltose, mannitol, or sorbite; it produces neither acidity nor gas in these substances.

Action on Maltose.—*B. typhosus* alone produces acidity only, never gas; *B. proteus* (P) alone produces neither acidity nor gas; their mixture produces acidity and gas.

Action on Mannitol.—*B. typhosus* produces acidity, never gas, *B. proteus* (P) has no action on it; neither acidity nor gas is produced. Their mixture, however, produces acidity and gas.

TABLE II.

	Lactose	Saccharose	Glucose	Levulose	Maltose	Galactose	Mannitol	Sorbite
B. typhosus	O	O	A	A	A	A	A	A
B. proteus (P)	O	O	AG	AG	O	AG	O	O
B. typhosus + *B. proteus* (P)	O	O	AG	AG	AG	AG	AG	AG

O = negative, neither acid nor gas; A = acid; G = gas.

Action on Sorbite.—*B. typhosus* produces acidity only; *B. proteus* neither acidity nor gas; their mixture causes production of acidity and gas.

B. DYSENTERIÆ FLEXNER + B. MORGANI.

Action on Mannitol.—*B. dysenteriæ* Flexner produces acidity only, never gas. *B. morgani* has no action on it; neither acidity nor gas is produced. The mixture *B. dysenteriæ* + *B. morgani* produces acidity and gas.

Action on Maltose.—*B. dysenteriæ* Flexner produces only acidity, never gas; *B. morgani* produces neither acidity nor gas; their mixture produces acidity and gas.

B. DYSENTERIÆ FLEXNER + B. PROTEUS.

Action on Mannitol.—*B. dysenteriæ* Flexner produces acidity, never gas; *B. proteus* (P) produces neither acidity nor gas; their mixture produces acidity and gas.

Action on Maltose.—*B. dysenteriæ* Flexner produces only acidity, never gas; *B. proteus* (P) produces neither acidity nor gas; their mixture produces acidity and gas.

TABLE III.

	Lactose	Saccharose	Glucose	Levulose	Maltose	Galactose	Mannitol	Sorbite
B. dysenteriæ Flexner	O	O	A	A	A	A	A	O
B. morgani	O	O	AG	AG	O	AG	O	O
B. proteus (P)	O	O	AG	AG	O	AG	O	O
B. dysenteriæ Flexner + *B. morgani*	O	O	AG	AG	AG	AG	AG	O
B. dysenteriæ Flexner + *B. proteus* (P)	O	O	AG	AG	AG	AG	AG	O

O = negative, neither acid nor gas; A = acid; G = Gas.

B. TYPHOSUS + B. MORGANI + B. PROTEUS.

Action on Maltose, Mannitol and Sorbite.—*B. typhosus* alone produces acidity, no gas. *B. morgani* alone produces neither acidity nor gas. *B. proteus* (P) alone produces neither acidity nor gas. The mixture *B. morgani* + *B. proteus* (P) produces neither acidity nor gas. The mixture of the three germs produces acidity and gas.

B. COLI COMMUNIOR + B. KANDIENSIS (var. *kandiensoides*).

Action on Adonite.—*B. coli communior* produces neither acidity nor gas; *B. kandiensis*, acidity only, never gas. The mixture *B. coli communior* + *B. kandiensis* will produce acidity and gas, although slowly. The tubes must be kept at 37° for at least a week.

STAPHYLOCOCCUS AUREUS + B. MORGANI.

Action on Maltose.—*Staphylococcus aureus* alone (Ross Institute strain) produces acidity, no gas, in maltose; *B. morgani* alone produces neither acidity

nor gas. The mixture *Staphylococcus aureus* + *B. morgani* produces acidity and gas.

STAPHYLOCOCCUS AUREUS + B. PROTEUS.

Action on Maltose.—*Staphylococcus aureus* alone (Ross Institute strain) produces acidity, no gas, in maltose; *B. proteus* alone produces neither acidity nor gas. The mixture *Staphylococcus aureus* + *B. proteus* produces acidity and gas.

STREPTOCOCCUS PYOGENES + B. MORGANI.

Action on Maltose.—*Streptococcus pyogenes* (strain Public Health Laboratory, London) alone produces acidity, no gas; *B. morgani* produces neither acidity nor gas. The mixture *Streptococcus pyogenes* + *B. morgani* produces acidity and gas, but it may take eight or ten days at 37° C. before the gas appears.

STREPTOCOCCUS PYOGENES + B. PROTEUS

Action on Maltose.—*Streptococcus pyogenes* (strain Public Health Laboratory, London) alone produces acidity, no gas; *B. proteus* produces neither acidity nor gas. The mixture *Streptococcus pyogenes* + *B. proteus* produces acidity and gas, but it may take eight or ten days at 37° C. before the gas appears.

BACILLUS VERMICULOIDES + CRYPTOCOCCUS GRACILOIDES.

These two organisms live apparently in symbiosis and it took me more than a year to separate them. The symbiotic mixture produces gas, though very slowly, in glucose, levulose, and maltose. The cryptococcus alone does not produce either acid or gas in these sugars or any other carbohydrates; the bacillus alone produces acidity only.

or close association with *B. typhosus* it apparently loses its fermentative power on saccharose. The mixture *Monilia tropicalis* + *B. typhosus* produces no fermentation of saccharose peptone water.

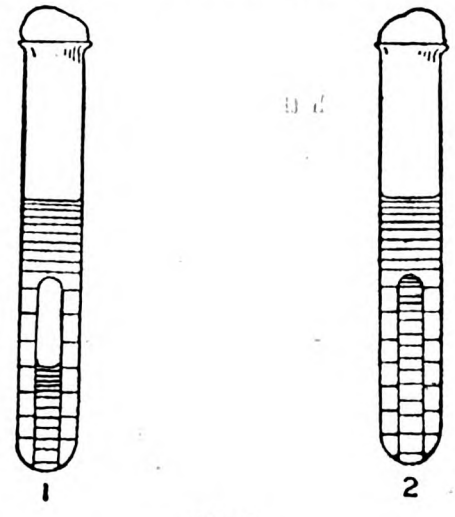

FIG. 3.

1. Saccharose peptone water inoculated with *Monilia tropicalis*. Gas present.

2. Saccharose peptone water inoculated with *Monilia tropicalis* + *Bacillus typhosus*. Gas absent.

Monilia krusei alone gas-ferments glucose rapidly and abundantly. *Bacillus talavensoides* alone does not gas-ferment glucose or any other sugar. When *M. krusei* is grown together with *B. talavensoides* no fermentation of glucose takes place. The mixture *M. krusei* + *B. talavensoides* does not produce gas fermentation in glucose peptone water.

TABLE IV.

	Lactose	Glucose	Levulose	Maltose	Galactose	Saccharose	Mannite	Dulcite	Salicin	Inosite	Dextrin	Inulin	Sorbite	Adonite	Arabinose	Raffinose	Isodulcite	Erythrite	Glycerine	Gelatine
Cryptococcus graciloides Castellani	O	O	O	O	O	O	O	O	O	O	O	O	O	O	O	O	O	O	O	O
Bacillus vermiculoides Castellani	A	A	A	A	A	O	O	O	O	O	O	O	O or A *v.* S	O	O	O	O	O	O	O
Cryptococcus graciloides + *B. vermiculoides*	A	AG	AG	AG	A	O	O	O	O	O	O	O	O	O	O	O	O	O	O	O

A = acid; G = gas; O = absence of gas or coagulation; S = slight.

Symbiosis producing Inhibitory Phenomena.—The experiments I have described above show what might be called the activating effects of symbiosis. It may perhaps be of interest to quote experiments which show certain inhibitory effects of symbiosis. The following examples will suffice for the purpose of this paper.

Monilia tropicalis ferments saccharose with production of gas. *B. typhosus* does not ferment saccharose. When *Monilia tropicalis* lives in symbiosis

Monilia krusei produces gas in glucose; the mixture *Monilia krusei* + *B. talavensoides* does not.

Résumé and Conclusions.—Some years ago I found that the usual "baker's yeast," as obtainable in Ceylon and in England, is not a pure culture of yeast, but is generally composed of two or more species of *Saccharomyces* and one or two or several species of bacteria living in close association, and I made the observation that the whole yeast, as a rule, gas-fermented more carbohydrates than any of

the isolated germs did, either saccharomyces or bacteria. I found also that a bacillus (isolated from a sample of yeast) which produced acidity only, not gas, in maltose, would produce gas when I added to it a saccharomyces which was inactive on maltose and was isolated from the same sample.

In recent years I have used for my experiments mostly pathogenic bacteria and also a pathogenic yeast, *Cryptococcus graciloides*. Two organisms neither of which produces alone gas fermentation in certain carbohydrates may do so when mixed together. This phenomenon has been called by Fiallos "Castellani's fermentation phenomenon."

Simple acid fermentation of certain carbon compounds caused by micro-organisms which never produce gas may in a number of instances be transformed into fermentation with the production of gas by adding a micro-organism which, alone, is inert, viz., produces neither acidity nor gas on those particular carbon compounds. For example: *B. dysenteriæ* Flexner produces acidity, never gas, in maltose and mannitol; *B. morgani* produces neither acidity nor gas in these two carbohydrates; the mixture *B. dysenteriæ* Flexner + *B. morgani* produces, however, acidity and gas. The explanation of these phenomena, as pointed out recently by Schütze and Harde, lies probably in the fact that one of the organisms produces certain substances which are fermentable by the other organism.

In addition to activating phenomena symbiosis may give rise to inhibitory phenomena. For instance, *M. krusei* seems to lose its fermentative action on glucose when grown together with *B. talarensoides*.

The Importance of Close Association of two Organisms in the Ætiology of certain Diseases and in the Causation of certain Symptoms.—The whole trend of scientific medicine since Pasteur and Koch has been toward the mono-ætiology of disease—one disease, one specific germ. Few medical men ever give a thought to the possibility that certain diseases may be caused by the association of two organisms, neither of which alone is capable of producing the condition. Do diseases of this type really exist? One such disease has been known for years, viz., Plaut-Vincent's angina, caused by the association of two germs, a spirochæte and the fusiform bacillus, but objections have been brought forward against the condition being of true symbiotic origin. Certain authors, with whom I do not agree, consider the two so-called organisms to be different stages of the development of the same germ. Another objection of greater weight to the true symbiotic origin of the malady is that, according to certain observers, there are cases in which only the spirochæte or only *B. fusiformis* is present. A third objection is that in every case of so-called Plaut-Vincent's angina, a very large number of cocci and usually also various bacilli are present; it is not, therefore, merely a symbiosis between a spirochæte and the fusiform bacillus.

I venture to say that I am in a position to bring forward three examples of disease in which a symbiosis, or close association of two organisms, is apparently the true cause. These three diseases are of very little importance from a practical point of view, but I think they are interesting from a scientific standpoint. These conditions are:

(1) *Trichomycosis nigra.*
(2) *Trichomycosis rubra.*
(3) *Stomatitis Cryptococco-bacillaris.*

Trichomycosis nigra is a disease of the hair of the axillary and pubic regions, characterized by the presence on the shaft of the hair of small nodules of a jet-black colour. The microscopical examination of these nodules shows that they are composed of enormous numbers of bacillary bodies of a fungus (*Nocardia*), which I called *Nocardia tenuis*, and large numbers of a black pigment-producing coccal organism, *Micrococcus nigrescens* Castellani. We have here, therefore, an association between a fungus, *Nocardia* + a coccus. The fungus alone does not produce tinea nigra; it has no pigment.

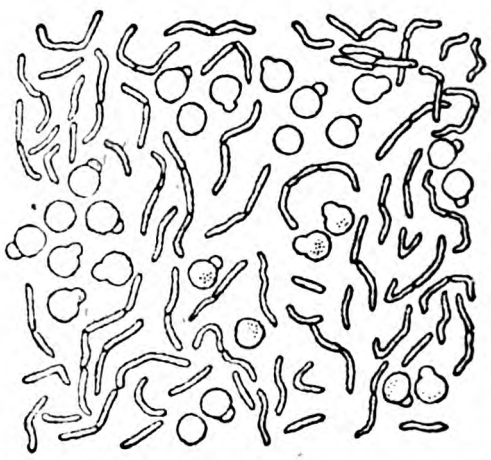

FIG. 5.—*Cryptococcus graciloides* and *B. vermiculoides* in symbiosis.

When the fungus is present alone the nodules are yellow (*Trichomycosis flava, leptothrix*). The micrococcus alone cannot reproduce the disease. I have never seen nodules consisting of the coccus alone; the coccus can be artificially grown; cultures smeared in various ways on the armpits and axillary hairs have never produced the nodular condition. Tinea nigra, therefore, may be considered to be caused by a symbiosis of two organisms, neither of which alone is capable of producing the typical condition.

DESCRIPTION OF NOCARDIA TENUIS.

Nocardia tenuis Castellani 1912. (Syn.: *Discomyces, Streptothrix, Cohnistreptothrix tenuis* Castellani 1912.)

The microscopical examination of the nodules in cleared specimens reveals the presence of enormous numbers of rod-like bodies—the bacilliform hyphæ of a Nocardia—which are Gram-positive, but not acid-fast. If the nodules are kept in alcohol or formalin for several months the fungus apparently loses partially or totally its property of being stainable by Gram's method. The bacillary

bodies vary in length from 2 to 8 microns and more; the average breadth is approximately 0·14 to 0·3 microns; they may be straight or slightly bent, very seldom if ever branching; they are fairly closely packed together, and are embedded in a cementing substance, apparently secreted by the fungus. This ground substance is fixed to the cortex of the hair, and a portion of it lies under the cuticle and some of the superficial layers of the cortex. In regard to cultivation, Chalmers and O'Farrell observed some slight growth in hanging drops of equal parts of human serum and normal saline. The fungus grew, showing branching forms and coccal forms. The branching was monopodial and the hyphæ were non-septate. Macfie, in one case, succeeded in cultivating the fungus on ascitic sugar agar, the colonies being very small and translucent.

Micrococcus (Nigrococcus) nigrescens, Castellani 1912.

This is a Gram-positive, rather large, non-motile coccus, which in certain media may take the appearance of coccobacillus. It produces a black pigment. Sugar media are more suitable for the growth of the organism than the ordinary agar.

Sabouraud Maltose Agar.—Colonies appear twenty-four to forty-eight hours after inoculation. They are roundish, at first white, but after a couple of days the centre of each colony turns black, and the pigmentation slowly spreads eccentrically. After a time the colonies may coalesce into a jet-black mass.

Glucose Agar.—Growth similar to Sabouraud, but slightly less abundant. The black pigmentation develops from the centre of each colony and slowly spreads towards the periphery.

Levulose Agar.—Identical to glucose.

Saccharine Agar.—The pigmentation is less pronounced, and does not spread to the whole of the growth.

Raffinose Agar.—Same as saccharine.

Lactose Agar.—Scanty pigmentation.

Alkaline Maltose Agar.—Black pigmentation well marked, though in many cases it does not extend to the whole of the growth.

Acid Maltose Agar.—Growth less abundant than on alkaline maltose. Black pigmentation well marked.

Mannite Agar.—As alkaline maltose.

Inulin.—As alkaline maltose, but pigmentation less pronounced.

Saccharose.—As inulin agar.

Glycerine Agar.—Abundant growth, the whole of which after a time becomes a jet-black colour.

Galactose.—As inulin.

Adonite.—As acid maltose.

Ordinary Agar.—Growth much less abundant than on most sugar agars, and black pigmentation less marked.

Serum.—Growth fairly abundant, but there is only a trace of pigmentation. The medium is not liquefied.

Gelatine.—No liquefaction. The growth on the surface shows after a time and some dark pigmentation, but the growth along the stab is white.

Milk.—No change.

Broth.—General turbidity. A thin pellicle is often present. The microscopical examination shows cocci arranged in pairs or irregularly. They do not appear to be capsulated.

Peptone Water.—Some growth at the bottom, while the rest of the tube is clear.

Sugar Broths.—No formation of acid or gas.

Indol.—Most strains produce a trace of indol.

Trichomycosis rubra is a somewhat similar condition to tinea nigra, but the nodules are of a bright red colour. The microscopical examination of these nodules shows that they are composed of a nocardial fungus, identical to that found in tinea nigra, plus a coccal organism present in large numbers and producing a red pigment. The fungus alone produces yellow nodules, never the red pigmentation; the coccus alone produces red pigment, but is not capable of producing the nodules. For the disease to develop, it is apparently necessary to have the two organisms closely associated, and tinea rubra can, therefore, be considered an example of disease of symbiotic origin.

Description of Micrococcus castellanii, Chalmers and O'Farrell 1913.

Syn. *Rhodococcus castellanii*, Chalmers and O'Farrell 1913.

This coccus, isolated in 1910 by me from the red variety in Ceylon, and later further investigated in the Sudan and named by Chalmers and O'Farrell, is more difficult to isolate and to grow than the coccus observed in the black type of the affection. It is interesting to note that as a rule it grows better and shows more pigment on ordinary agar than on sugar media. It is a round or oval coccus, measuring from about 0·3 to 0·7 micron in diameter. It is separated medianly by a clear central line into two half-moon-shaped segments, thus producing a diplococcal appearance. It is colourless and non-motile, but excretes an amorphous, non-granular lemon-chrome-coloured pigment. In old cultures another pigment of dark brownish-red colour appears (according to Ridgway's standards this colour is madder-brown), but its relationship to the earlier yellow pigment can easily be proved, as demonstrated by Chalmers and O'Farrell, by removing some of it and suspending it in a sufficiency of distilled water, when the fluid at once resembles a similar suspension of the yellow pigment. When, however, this is done in a very small quantity of water, a faint reddish tinge can be observed. The best medium for showing the striking yellow pigment is the potato, when in twenty-four hours the growth assumed that colour. The red pigment shows best in the ordinary agar slope, which, when old, exhibits the dark red pigment in the centre and the yellow pigment at the sides. The organism is easily stained by all the ordinary staining reagents, and is Gram-positive. However, even in preparations showing most of the cocci well coloured by Gram's methods a few cocci may be seen decolorized, and occasionally one may see cocci with one demilunar segment well stained, while the other is completely decolorized. The organism does not appear to have a capsule.

The coccus grows aerobically and also anaerobically. The optimum temperature appears to be 37° C.; it also grows at 20° C. on agar slopes, but not as abundantly as at 37° C., and the pigmentation is much less marked. Its rate of growth depends somewhat upon the medium; it grows quickest on potato, and next best on ordinary or glycerine agar. On solid media it gives rise to a yellow growth at first, but on most media, if kept long enough, some red coloration will subsequently be found. The best medium for the red coloration, as already stated, appears to be ordinary agar slope. With regard to the other agar media, it grows well on glucose and maltose agar. Like *M. nigrescens* it produces neither acid nor gas in glucose, levulose, galactose, arabinose, lactose, saccharose, raffinose, dextrin, inulin, amygdalin, erythrite, adonite, dulcite, isodulcite, mannite, sorbite, or inosite. It grows slowly on blood-serum, which does not liquefy, and well in broth and peptone water, in which it forms a general turbidity. Gelatine is not liquefied. It does not produce indol.

In agar stabs the growth is confined to the line of puncture and to the formation of a small yellow knob on the surface.

Classification of Micrococcus castellanii.—Chalmers and O'Farrell have thoroughly investigated this point: "The organism belongs to the family *Coccaceæ* (Zopf, emended Migula), and must be grouped with the genus *Micrococcus* (Hallier, 1866, emended Cohn, 1872). In this genus it certainly belongs to those forms which grow well on agar media and are Gram-positive, and in this division it belongs to the subdivision which produces colours.

"The cocci of this subdivision which possess red coloration are only three in number: *M. roseus* (Baum, 1885),

M. ruber (Trommsdorff, 1904), and *M. rubidus* (Hefferen). Under the term *M. roseus* (Baum, emend. Lehmann and Neumann) are gathered a large number of rose-coloured diplococci which are not known to be parasitic, and which produce growths on potato which are limited to the streaks. These growths are faint rose colour with an oily lustre and are often surrounded by a whitish glistening zone, thus giving rise to a very different appearance from that produced by *M. castellanii*. *M. ruber* (Trommsdorff, 1904), or, as it is sometimes named, *M. chromidrogenus ruber*, is characterized by the fact that it does not grow on potato; its colouring matter is not soluble in water, and when treated by sulphuric acid the red colour turns blue-green, while *M. castellanii* does grow on potato and its colouring matter is unaffected by 25 per cent. sulphuric acid; it appears to be closely related to *M. roseus* var. *carneus*, and to be non-parasitic."

Stomatitis cryptococco-bacillaris.

The appearance of the lesions is quite different from thrush. The patches, which are generally of large dimensions, are hardly raised at all, and are not cream-white; they have the appearance of a thin translucid whitish film covering parts of the oral mucosa, occasionally giving the impression of being patches of incipient diffused leucoplakia, but the microscopical examination of scrapings will clear the diagnosis. The first two cases of this stomatitis I observed in Central America; very recently I have seen a case of the same, or of a very similar condition, in England, but the investigation of this case has not yet been completed.

From these cases of stomatitis, clinically totally different from thrush, I have isolated a fungus and a bacillus which apparently live in symbiosis, both in the lesions and in the cultures. In glucose agar cultures a number of minute, almost streptococcus-like colonies will be seen. The microscopical examination of any of these colonies will show presence of both the delicate yeast-like fungus and the bacillus. For many months I did not succeed in separating the two organisms by plating and various other devices. I noticed that a high temperature (37° C.) increased the growth of the bacillus, while a low temperature was somewhat unfavourable to it. I noticed also that in MacConkey lactose agar tubes the fungus had a tendency to become more scanty. Making use of these two observations by repeatedly inoculating MacConkey lactose agar tubes and keeping some of them at 37° C., others at 15 to 22° C., I succeeded finally in separating the two organisms, of which I will here give a brief description.

(A) *Yeast-like Fungus* (*Cryptococcus graciloides*, Castellani 1925).—Very delicate yeast-like organism, Gram-positive, not acid-fast. Each cell is roundish, or more often oval, with frequently a flask-like shape. In preparations from the cultures the average maximum longitudinal diameter of most cells is 3 to 4·5 microns, and the maximum average transverse diameter is 2 to 3 microns.

Cultural and Biochemical Characters.

Glucose Agar.—Minute colonies somewhat streptococcus-like.

MacConkey Lactose Agar.—Minute colonies, but growth often more abundant than on glucose agar.

Gelatine and Serum.—Growth exceedingly scanty; neither of the media is liquefied.

Lead Agar.—No evident darkening of the medium.

Glucose and Other Sugar Peptone Waters.—Apparently no production of acidity or gas, but the organism grows extremely scantily in these media, and sometimes no growth at all takes place.

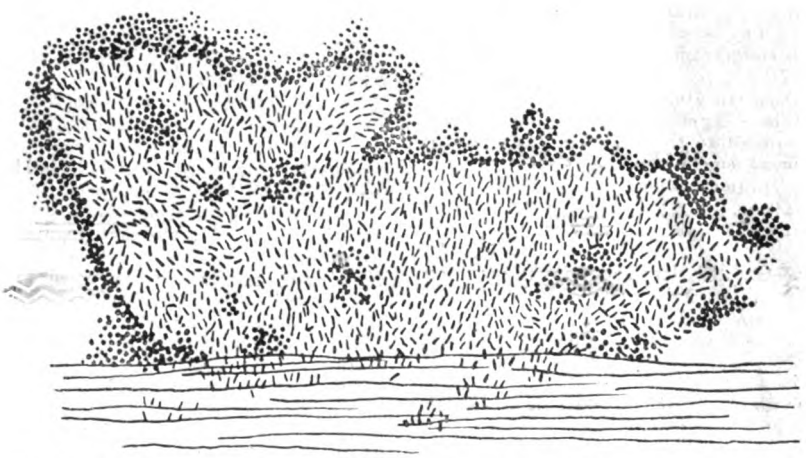

FIG. 4.—Trichomycosis nigra. Note masses of bacillary hyphæ of *Nocardia tenuis* and masses of black pigment-producing coccus.

Classification of the Organism.—As the fungus is morphologically yeast-like, it comes under the general heading "Yeast-like Fungi."

This yeast-like fungus never shows presence of asci; mycelium is completely absent; the budding takes place by one budding at a time; the organism does not produce a thick pellicle in fluid-sugar media; it should therefore be placed in the genus *Cryptococcus*. The peculiar flask-like appearance often shown by this fungus might be an argument to place it in another genus, the genus *Pityrosporum* Sabouraud 1895, which is said to differ from the genus *Cryptococcus* as follows:—

(1) The vegetative cells have a flask-like appearance and do not show a well-marked double contour.

(2) It has not been cultivated.

The genus *Pityrosporum* Sabouraud 1895 contains two species, *Pityrosporum ovale* Bizzozzero 1882 and the *Pityrosporum cantlei* Castellani 1908. Morphologically the fungus I have isolated is very similar to *P. ovale*, but it differs from it in the fact that it is of smaller dimensions and is cultivable, and, moreover, certain cells may show a double contour. In my opinion the fungus should be placed in the genus *Cryptococcus*.

(B) *Bacillus vermiculoides* (n.s.).—This bacillus apparently lives in symbiosis with the *Cryptococcus* I have described; I have separated the two organisms with great difficulty, but I now have pure cultures of both. The bacillus is of rather large dimensions, its length varying between 2 and 6 microns; it is often curved in shape. It is Gram-positive, not acid-fast. The optimum temperature seems to be 37° C., but it may grow, though much less abundantly, at a much lower temperature, 22° C., and even less.

Glucose Agar.—Minute colonies somewhat resembling those of certain streptococci.

Gelatine.—Growth very scanty, or absent altogether; no liquefaction.

Serum.—No liquefaction of the medium.

Sugar Peptone Waters.—It produces acidity, but no gas in glucose, levulose, maltose, galactose, and lactose. There is usually no change in the other sugar-peptone waters.

Litmus Milk.—The medium is rendered acid and after a time may become clotted.

Biochemical Reaction of the Associated Organisms.—When sugar media are inoculated with a mixed cryptococcus-bacillus culture, acid and gas are produced, though very slowly, in glucose and levulose; acidity only in lactose, maltose and galactose; litmus milk is rendered acid and clotted. The cryptococcus alone produces no change in any carbohydrate; the bacillus alone produces acidity (no gas) in several carbohydrates.

Symbiosis may play a Rôle in the Causation of certain Symptoms of Disease.—Let me remind the reader that I use the term symbiosis *sensu lato*, that is to say, to denote the close association of two micro-organisms. There is little doubt that in certain diseases due to specific germs, some so-called typical symptoms are not due to the action of the specific germ *per se*, but to the action of the specific germ plus a non-specific germ living in association. Let me bring forth an example such as occurs in everyday practice—scabies. The typical pustular eruption is not caused by the acarus *per se;* it is caused by pyogenic cocci which apparently find the proper condition to multiply and become virulent on the skin irritated by the acarus; and also the acarus may act as carrier for the pyogenic germs. In individuals who wash their hands frequently with disinfectants, such as nurses and surgeons, when they become occasionally affected with scabies pustules are generally absent and the diagnosis may be extremely difficult.

I will mention another condition described and experimentally studied by me some years ago, viz., *copra itch*. This is a condition found in individuals handling copra, and it is caused by a mite present in millions in copra dust. The disease, apart from the presence of burrows, is identical with scabies. The patient complains of terrible itching and a papulo-pustular eruption is generally present. The pustular eruption is caused by the pyogenic organisms, not by the mite *per se* (*Tyroglyphus longior*, var. *castellanii* Hirst).

Yaws.—In all textbooks the statement is found that one of the typical symptoms is the presence of the large nodules capped by thick, bright yellow crusts. These thick, bright yellow caps are not produced by the specific germ of yaws, *Treponema pertenue*, but by associated pyogenic cocci. If the incipient nodules are constantly dressed with perchloride lotion, they enlarge and become the same size as the other nodules, but the yellow crust is practically absent.

Typhoid.—Meteorism, as is well known, is caused to a great extent by defective tone in the intestinal walls. According to certain researches I have carried out, however, the great abnormal distension found in some cases of typhoid may be caused by the association of the typhoid bacillus with other bacilli, especially bacilli of the Morgan group. In two cases, in which the abnormal distension was extremely marked, the bacteriological examination of the fæces revealed the presence of *B. typhosus* and *B. morgani* closely associated, viz., numerous colonies on MacConkey's plates, which seemed to be pure, were composed in reality of the two germs living in symbiosis. Now *B. typhosus* alone produces no gas in any carbon compound, *B. morgani* alone in only a very few. Their mixture in a much larger number.

The Smell of Favus.—The typical smell—so-called mousy smell—found in so many cases of favus is well known. From certain experiments that have been carried out, it would appear that it is not due to the fungus of favus directly, but to associated bacteria which find the favourable conditions of growth in the lesions caused by the Achorion.

Conclusions.—In conclusion, it would appear that symbiosis or the close association of two or more organisms may play an important rôle in biochemical phenomena and in the causation of certain diseases and certain symptoms of disease.

Biochemical Phenomena.—Symbiosis may play an important rôle in fermentation phenomena. As I observed long ago in Ceylon, ordinary baker's yeast *in toto*, which is in reality a symbiosis between one or more saccharomyces and one or more bacteria, gas-ferments in many cases a larger number of carbohydrates than any of the isolated organisms

The mixture *B. typhosus* + *B. morgani* will produce gas in maltose, mannitol and sorbite, while *B. typhosus* alone produces only acidity (never gas) and *B. morgani* alone has no action, viz., does not produce either acidity or gas in these substances.

In addition to activating phenomena, symbiosis may cause inhibitory effects; for instance, *Monilia tropicalis* produces fermentation with gas, of saccharose, but when grown in symbiosis with *B. typhosus* it seems to lose this property.

Diseases.—It seems certain that there are diseases caused by a true symbiosis or association of two organisms, neither of which alone is capable of producing the malady. Trichomycosis rubra, trichomycosis nigra, stomatitis cryptococcus-bacillaris are examples of such diseases.

Symptoms of Disease.—Certain so-called typical symptoms of diseases of which we know the specific organisms, are in all probability due not to the specific germ alone, but to the association of the specific germ plus one or more non-specific organisms. The mouldy or mousy smell of favus is not caused directly by the fungus, but by associated organisms; the typical honey-yellow crusts of yaws seem to be caused by the pyogenic cocci associated with the

specific germ, *Treponema pertenue*. The great abdominal distension in certain cases of typhoid is probably due to defective tone in the intestinal walls, but may be caused or increased to a certain extent by the association of certain bacilli, as for instance, *B. morgani*, to the typhoid bacillus.

A NEW SPECIES OF *HEPATICOLA* (NEMATODA) FROM THE RAT'S STOMACH.

By H. A. BAYLIS, M.A., D.Sc.

Department of Zoology, British Museum (Natural History).

Published by permission of the Trustees of the British Museum.

ON two occasions reference has been made by the writer (1925 *a* and *b*) to a Nematode found in the lining of the stomach of rats, which was believed to be *Hepaticola hepatica* (Bancroft, 1893). This worm was found by the writer in a rat (*Rattus norvegicus*) at Bologna, Italy. It has more recently been found to occur very frequently in rats (both *R. norvegicus* and *R. rattus*) at Villa Lagarina, near Rovereto, in the Trentino. Specimens collected by Dr. Wassink in Holland have been identified with it, and what was probably the same species has been recorded by Fibiger in Denmark.

Dr. Sambon, who has always been much impressed with the importance of habitat in relation to questions of specificity among parasites, expressed a conviction that this stomach parasite must be distinct from the liver-inhabiting *H. hepatica*. This question, however, could not be decided without a careful comparative study.

Closer examination reveals certain differences from *H. hepatica*, and it appears necessary to describe the worm as a new species. The absence of a spicule in the male seems to warrant its inclusion in the genus *Hepaticola* Hall, 1916, which differs in this character from the other genera of the subfamily Trichurinæ (see Hall, 1916, pp. 19, 30). Apart from this it might probably be referred to *Capillaria*.

The worms inhabit tortuous galleries in the epithelium lining the anterior, or cardiac, portion of the stomach of the host. They evidently wander about considerably, as this part of the stomach is frequently found to be tunnelled extensively with deserted galleries, in which numerous eggs have been deposited by the female worms. Complete and undamaged specimens are difficult to obtain even by careful dissection of fresh stomachs, owing to the extreme slenderness and fragility of the worms and the relative toughness of the overlying epithelium. The following brief description is based chiefly on two males and one female obtained in this way.

Hepaticola gastrica, sp. n.

The male attains a length of at least 22·4 mm. and the female 37·1 mm. The maximum thickness

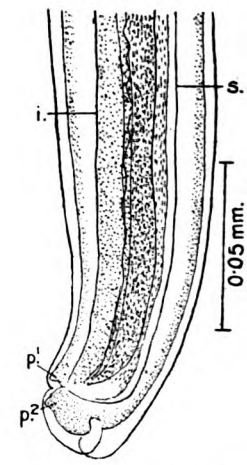

FIG. 1.—*Hepaticola gastrica*. Caudal end of male; lateral view. *i.*, intestine; p^1., preanal papilla; p^2., postanal papilla; *s.*, spicule-sheath.

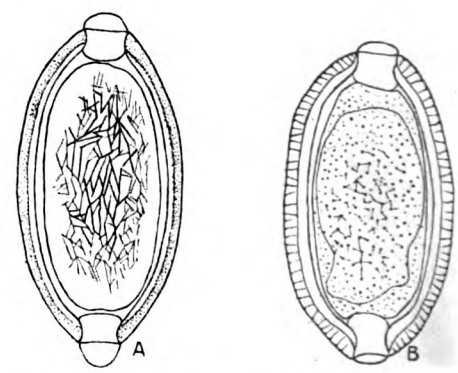

FIG. 2.—Eggs of *Hepaticola gastrica* (A) and *H. hepatica* (B), drawn under the same magnification (Zeiss oil-imm. $\frac{1}{12}$) to show the surface pattern of the shells.

of the male is about 0·065 mm., that of the female 0·09 mm. The diameter at the extremely slender anterior extremity is from 0·007 to 0·01 mm., and at the anus 0·032 to 0·035 mm. in the male and 0·025 mm. in the female. The cuticle has extremely fine transverse striations. The œsophagus is only distinguished with difficulty from the intestine. Its extent, especially in the male, is rather doubtful. In one male it appeared to end at 2·15 mm. from

the anterior extremity, while in the female a more definite line of demarcation occurred at 6·9 mm. from the head end.

The caudal end of the male is bluntly rounded, and appears to terminate in three cuticular lobes, one of which is dorsal and two ventro-lateral. Into the ventro-lateral lobes parenchymatous masses extend, each of which appears to carry a small subventral postanal papilla. There is a long spicule-sheath, which has not been observed in an everted condition, and which appears to contain no spicule. In the introverted condition the sheath is lined with minute spines, which become larger for a short distance towards its anterior end. This region would presumably become the posterior extremity of the sheath when everted, and would probably form a spiny bulb.

In the female the vulva is situated immediately behind the apparent termination of the œsophagus, and from it the vagina and the single uterus run directly backwards. The vulva has rather prominent lips. The uterus contains a single or double row of relatively large eggs, which are longer than the diameter of the lumen, and therefore must lie either parallel to its axis or obliquely to it. The caudal end of the female tapers rather suddenly, but ends in a bluntly rounded and extremely short tail, the anus being subterminal.

The eggs afford the most satisfactory characters for separating this species from *H. hepatica*. The existing descriptions of *H. hepatica* are somewhat conflicting as to the dimensions of the eggs. Bancroft (1893) gives them as 55 microns × 30 to 35 microns. Leidy (1891), in his description of *Trichosomum tenuissimum*, which is probably the same worm, states that the eggs measure 0·04 mm. × 0·032 mm. Travassos (1915) gives the measurements of the eggs of *Capillaria hepatica* (Railliet, 1889), which is again the same species, as 3·060 mm. × 0·028 mm., the extraordinary measurement of the length being evidently due to a printer's error. Hall (1916) states that he finds 52 microns the maximum length of eggs of *H. hepatica*. The writer, however, finds that eggs from the livers of rats, believed to be those of *H. hepatica*, measure from 62·5 to 67·5 microns in length, and from 30 to 32·5 microns in width. The eggs of *H. gastrica*, on the other hand, measure 70 to 72·5 microns × 27·5 to 30 microns. They are thus, on the average, a little longer and a little narrower than those of *H. hepatica*. They are also more regularly lemon-shaped or boat-shaped in outline, those of *H. hepatica* being rather oblong. The extent to which the polar plugs of the shell project is rather variable in both species, and affects the measurements of length considerably. The two layers of the shell are considerably thinner in *H. gastrica* than in *H. hepatica*.

But the most distinctive specific character is found in the surface pattern or ornamentation of the egg-shells. The appearance of "striation" in the shell of the egg of *H. hepatica*, in optical section, has frequently been observed. This seems to be due to minute rod-like structures running through the thickness of the outer shell more or less perpendicularly to the surface, where they appear to end in little refringent knobs or points. These give the surface of the shell a punctate appearance when accurately focused under high powers of the microscope. The refringent points are also connected here and there by very fine lines, giving the appearance of a very fine, irregular network. In the eggs of *H. gastrica* the outer shell lacks the pronounced appearance of striation in optical section, but is somewhat granular. On the surface there is a pattern composed of fine straight lines or ridges running in various directions and forming a network of quite different character from that of *H. hepatica*. The refringent points, and the vertical rod-like structures of which they are the expression in *H. hepatica*, are here absent.

Thus, although the morphological characters of the adult worm do not at present afford very conclusive evidence of its distinctness from *H. hepatica*, it seems necessary, on the ground of the differences in the eggs, to regard the stomach-inhabiting *H. gastrica* as specifically distinct from the liver-inhabiting *H. hepatica*.

HOOKWORM CONTROL WITH CHENOPODIUM-CARBON TETRACHLORIDE.[1]

By Henry R. O'Brien, M.D.

Bangkok, Siam.

Five years ago Hall [1] called attention to the value of carbon tetrachloride as an anthelmintic. The suggestion was at once caught up, and a succession of investigators have worked out the properties of this drug, both in the laboratory, with the help of dogs and other animals, and in the hospital, where a small number of patients under control could be treated and observed. Egg counts, worm counts, symptoms and autopsies have all contributed their information, until to-day we have a mass of in-

[1] The observations which form the basis of this paper were conducted with the support and under the auspices of the International Health Board of the Rockefeller Foundation.

formation about carbon tetrachloride, its dosage, efficiency and toxicity.

This information is of value to two classes of men. The private practitioner or hospital physician treats but one or two people at a time, individuals whom he has completely under his observation and control. The qualities which he especially desires in an anthelmintic are comfort and efficiency. The public health official has another problem. He must control infection in a whole population, by the treatment of large numbers of people. To do this he must frequently use non-medical men as dispensers, for an adequate supply of doctors is not available or is too expensive. For him the successful anthelmintic must have not only the two qualities mentioned above, but also those of economy and, above all, of safety. In addition, it must deal adequately with the mixed infection which is usually present. To-day he is studying the claims of carbon tetrachloride in the reports of the laboratory and hospital workers, and he asks the final question: "How does it work in the field, in mass treatments?" The first answer to this was furnished by Lambert [2] in his report of 50,000 treatments in Fiji, with three deaths. This paper reports further experience in another tropical field, on a still more extended scale.

The Hookworm Campaign in Siam.

For some years past the International Health Board has co-operated with governmental and other agencies in Siam in carrying on a campaign for the control of hookworm and other intestinal parasites, on the plan of mass therapy (sanitary improvement, of course, formed a phase of the work). Areas were selected because of their high infection rate, and treatments were given, without individual examination, to every able-bodied person who could be induced to present himself. Various drugs were used, but since May, 1925, by far the greatest number of treatments have been given with a mixture of chenopodium (40 per cent.) and carbon tetrachloride (60 per cent.). This mixture combined the efficiency of carbon tetrachloride in dealing with hookworms and the virtues of chenopodium in removing other parasites present. The dilution with carbon tetrachloride served to lessen the discomfort of taking the drug. The mixture was also considerably cheaper than chenopodium alone.

Every precaution was taken to guard the purity of the drugs. "Chemically pure" carbon tetrachloride was purchased in New York, but before being used was retested in the Government Laboratory in Bangkok, and when necessary redistilled and repurified. The chenopodium used was the standard article of good quality available in New York. The mixture was prepared by the field men by adding the measured volumes in quantities sufficient for several days' treatments. Just what deterioration takes place in the mixture on standing we do not know as yet, but instructions were issued to mix enough for only 3-4 days at a time.

Each field unit was composed of one Siamese physician and five or six dispensers. The latter were men of limited education, few of them having completed grade school; their training was also limited. But it is felt that so far as their background and training extended, they were able and conscientious men. These dispensers were scattered in villages about the county seat, and were frequently removed from their medical officer by several hours travel. They were thus thrown much on their own responsibility, both in conducting treatments and in dealing with any complications that arose.

Procedure.

The maximum dosage was 2 c.c. of the mixture. This was less than has been employed in some other countries, but the Siamese are a small people, and in an extended campaign a conservative dose seemed the wisest. The following routine was observed in giving treatments:—

(1) The patient went without breakfast.

(2) At 7 a.m. he was given half the dose of the mixture.

(3) At 8 a.m. he took the remainder.

(4) At 9 a.m. he drank an ounce of magnesium sulphate in hot water.

(5) He was then dismissed with the warning not to take food until after his bowels had moved.

In the case of a child of 15 years or younger the dose was two drops of the mixture for each year of apparent age, taken at one dose in castor-oil. Dispensers were directed to turn away applicants with tuberculosis, heart or kidney disease (they were given simple instructions in the more evident signs), those with acute conditions and pregnant women.

Results of this Series of Treatments.

The active use of this mixture of chenopodium and carbon tetrachloride in Siam began in May, 1925. Between that date and September 1, 1924 (shortly before the author left for his furlough) more than 225,000 individuals were treated with the mixture. This number is exclusive of cases in which for certain reasons other drugs were employed. It constitutes what is believed to be the largest series yet reported in which carbon tetrachloride was used.

In such a campaign a fatality is a thing most to be feared, not only in itself, but also in its effect on public sentiment. In connection with all these treatments with this drug, only three deaths were reported which, on investigation, were found to have no connection with the campaign treatment. Three others occurred, but of these one was a fractured skull in an old man who fell off a porch after treatment, one was a case of miliary tuberculosis (confirmed by post-mortem and examination of sections of liver), and the third was a case of overdose, a curious boy snatching a bottle and swallowing a mouthful of the mixture.

At the same time that this work was being carried on, Smillie and Pessoa [3] were finding that a dose of 2 c.c. of carbon tetrachloride (60 per cent.) and of ascaridol, the purified constituent of oil of chenopodium (20 per cent.) is "highly efficient, compara-

ively non-toxic, easy to administer, and inexpensive." The work in Siam, in which a similar mixture was used under remote campaign conditions, urnishes the field test. That we can report but hree deaths in treating so large a number with this nixture should be a satisfactory and reassuring nswer to the questions of public health workers lsewhere.

SUMMARY.

(1) A standard dose (2 c.c. maximum) of arbon tetrachloride (60 per cent.) and oil of henopodium (40 per cent.) was used in a mass herapy campaign in Siam.

(2) A total of 225,000 individuals were treated vith this mixture up to September 1, 1924, with hree deaths.

Experiments on the Administration of Quinine in Watery Solution in Olive Oil (J. O. Shircore, J. F. Corson and P. A. Clearkin).—According to the experiments of the authors, quinine sulphate in olive oil, administered intravenously to sheep is, weight for weight, 2·6 times less toxic than a watery solution of quinine bihydrochloride, and may be given up to a maximum of 0·65 gr. per pound of body weight without producing a fatal result.

Primary Carcinoma of the Liver (V. S. Counsellor and H. McIndoe, *Archives of Internal Medicine*, March 15, 1926).—Five cases of primary carcinoma of the liver are described; four hepatomas or primary carcinomas of the liver cells and one cholangioma or carcinoma of the bile ducts. The gross and microscopic appearances have little in common, as the massive, nodular and diffuse forms appear in any microscopic type. The massive form is, however, usually derived from liver cells. All the cases were associated with intrahepatic metastasis by way of the portal and hepatic veins, but in only two were there extrahepatic growths. No transitional forms were found, and the origin is therefore believed to be unicentric. All the cases were associated with cirrhosis of the portal type. The histories in three cases point to a preceding cirrhosis, and in all the microscopic examination of the connective tissue indicated a long-standing process. The relation between the hyperplastic liver tissue and the malignant cells is emphasized. From 3 to 4 per cent. of cirrhosis, particularly of the portal type, become carcinomatous.

Postage extra according to weight.

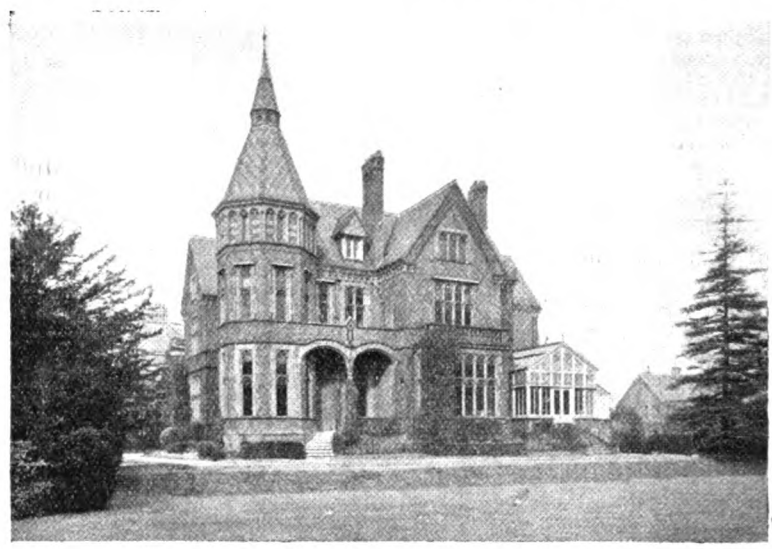
One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF

Tropical Medicine and Hygiene

AUGUST 2, 1926.



OPENING OF THE ROSS INSTITUTE.

THE Prince of Wales opened on Thursday, July 16, the Ross Institute and Hospital for Tropical Diseases, which has been established at Putney Heath, London, as a memorial to the life-work of

Sir Ronald Ross and as a centre of research and treatment.

His Royal Highness, on arrival, was received by the Duchess of Portland, president, and Sir Charles McLeod, Bart., and after inspecting the institute and hospital he proceeded to the platform in the pavilion. Sir Charles McLeod then presented an address of welcome to the Prince, which stated that the object of the institute was to advance research on every tropical disease and to hand on the results to the schools which taught the subject, both here and abroad, so that tropical and subtropical lands throughout the world might be delivered from the burden which now weighed so heavily on labour and industry and still more terribly on human life. General support had been forthcoming from business houses in all parts of the Empire, from Overseas Governments, and from the Prince of Wales himself.

"Of all these tropical enemies malaria has probably been the most deadly and the most elusive. But now, thanks to the achievement of one man, whose name we are perpetuating in this Ross Institute, its ultimate defeat is certain. Only a few months ago I was able to see in the Sir Alfred Jones Laboratory at Sierra Leone not only the vital need for a campaign against malaria, but also the remarkable progress which has already been made in it. Perhaps I am biased by many visits to tropical and subtropical parts of the world where malaria is rife, and by having talked with so many men and women whose health has been shattered by a life's work in such districts, but I can think of no other single discovery in recent times which will earn the deep gratitude of so many thousands of human beings of all nationalities as the discovery made in India by Major Ronald Ross—as he then was—on August 20, 1897. The story of its subsequent development

The Ross Institute and Hospital for Tropical Diseases, Putney Heath, London, S.W.

Sir Charles then handed His Royal Highness a gold key and asked him to declare the institute open.

The Prince of Wales, in reply, said:—

" The opening of this institute, which I am glad to perform, commemorates a definite achievement in the work which the British Empire has done for civilization. Not the least important obligation which the development of that Empire has laid on the members of our race is the constant struggle against disease in all the varied forms it can assume in different climates and in different latitudes. The struggle is always fiercest in the tropics, where man, and especially the white man, is the continual prey of diseases from which we in this country are, comparatively speaking, protected by a more temperate climate; and perhaps the saddest page in the whole history of our Empire is that which tells of the terrible toll taken by plague and by fever of those who helped to build it.

and of what it has led to is well known to you all I need only summarize it in the words of a famous writer: ' It is not too much to say that Sir Ronald Ross has made a third of the world inhabitable.'

" Over a quarter of a century had elapsed since that epoch-making discovery, and this institute and hospital now stands as a memorial to the life-work of Sir Ronald Ross and his colleagues. But it is not merely a passive memorial to work accomplished in the past; it is also, as Sir Charles McLeod has just reminded us, a very active centre for work to be done in the future. All who have any experience in the tropics will know that there is still a vast field for scientific medical research, and here, with all the resources that modern science can provide, such research can be effectively carried out, provided adequate funds are forthcoming. From this building may issue results which will bring back health to thousands who have lost it, or safeguard the lives of those countless others threatened

unseen dangers in tropical lands. More than at, it may open out, for the use and benefit of ankind as a whole, huge districts which are at esent denied to civilization.

"It is not surprising, therefore, that when the heme for founding this institute was first put rward it immediately received widespread public pport. That support happily made its inception ssible, and once the first financial obstacle was rmounted its promoters lost no time in making a reality. To the president, the Duchess of rtland, to Sir Charles McLeod and Mr. Shakeeare, and to Sir Ronald Ross and his two corectors, Sir William Simpson and Dr. Castellani, ie gratitude of all of us is specially due for the me and energy they have devoted to its execution. hey and their fellow officers of the institute may ell feel proud of the result of their labours and the knowledge that they have called into being mething which cannot fail to be of incalculable enefit to many generations.

"It is with the sincere hope that further public upport for the necessary endowment may be forthoming and that the labours of those who will work ere may be blessed with every success that I now eclare the Ross Institute and Hospital open."

The Duchess of Portland, in proposing a vote of hanks to the Prince of Wales, said that they were rateful for his appreciative and sympathetic words. He had spoken from personal knowledge and observation. His Royal Highness never shrank from any personal trouble in promoting philanthropic objects.

Sir Ronald Ross, Director-in-Chief, in seconding the motion, said that the words of the Prince would bring vividly before everyone in the British Empire some sense of the terrible loss which malaria inflicted on the world and some idea of the need to overcome it. He would like to acknowledge the ready and generous assistance given by more than 1,000 contributors, headed by His Royal Highness. Many of these were scattered throughout the Empire, and even beyond it. No fewer than fifteen of our tropical dependencies and as many as eight rulers of states had helped; hundreds of companies and business houses had added their names to the list and many private persons had assisted sometimes out of their humble incomes. He was most grateful for the kind manner in which the Prince had referred to his (Sir Ronald's) work. Hundreds of workers in the field of tropical medicine had "done their bit," if it were only in the trenches. He himself could only expect to view from afar the promised land of a perfectly sanitated world, but they must all endeavour to leave that institute in the best possible condition for future use as a centre for study and a home for sound research. The Prince of Wales, in reply, said he was only too happy to be associated with the institute and hospital, which was doing such a splendid work, not only in this country, but throughout the whole Empire.

The Ross Institute is a fine building standing in its own grounds on the border of the famous Putney Heath. There are two up-to-date wards and several splendidly equipped laboratories, and a good library.

The President of the Institute is Her Grace The Duchess of Portland; Chairman, Sir Charles McLeod, Bart.; Vice-Chairman, Mr. Walter Shakespeare; Director-in-Chief, Sir Ronald Ross; Directors, Sir William Simpson and Professor Aldo Castellani.

Several research workers have already taken advantage of the facilities offered by the institute and have carried out investigations on various subjects.

Annotations.

Syphilitic Myocarditis in the Rabbit (W. H. Brown and L. Pearce, *Journal of Experimental Medicine*, April 1, 1926).—In the course of routine post-mortem examinations of rabbits infected with *Treponema pallidum*, six cases of pronounced granulomatous myocarditis were encountered. Treponemata were not demonstrated in the lesions, but the clinical history, and the gross and microscopic appearance of the lesions, seem to warrant a diagnosis of syphilitic myocarditis. The lesions measured 1·0 cm. or more in diameter and histologically were practically identical with those described by Warthin in cases of syphilitic myocarditis in man. These are the first cases of syphilitic myocarditis or of visceral syphilis in the rabbit that have been reported.

Calcium Absorption from the Intestinal Tract in Human Subjects (B. S. Kahn and J. S. Roe, *Journal of the American Medical Association*, June 5, 1926).—This experimental study showed that calcium lactate administered orally to human subjects causes elevations of the blood-calcium level. 20 grm. doses gave an average maximum elevation of 81 per cent. between the fourth and fifth hours following administration, and a sustained elevation above normal for approximately four hours. 5 grm. doses gave an average maximum elevation of 80 per cent. between the sixth and seventh hours following ingestion, and maintained an elevation above normal for approximately nine hours. 2 grm. gave an average maximum elevation of 41 per cent. at the sixth hour following ingestion and a sustained elevation above normal for one and one-half hours. These findings are in disagreement with the work of many investigators, who have asserted that the blood-calcium concentration cannot be increased by the oral administration of calcium salts, and they confirm the work of Hjort, who found definite elevation of the blood-calcium in dogs given calcium salts by mouth. 5 grm. appears to be the dosage of calcium lactate that will give optimal results therapeutically.

Cultivation of Rickettsia-like Micro-organisms from the Rocky Mountain Spotted Fever Tick,

Dermacentor andersoni (H. Noguchi, *Journal of Experimental Medicine*, April 1, 1926).—A systematic study of seventy-four ticks, the infectivity or non-infectivity of which was determined by biting experiments, inoculation of emulsions, and specific immunity tests, showed the presence in some instances of several types of micro-organism of spotted fever. The most frequently isolated was *Bacterium rickettsiformis*, n. sp., those less commonly encountered were *B. pseudoxerosis*, n. sp., and *B. equidistans*, n. sp. These organisms are non-pathogenic for the guinea-pig, rabbit, or *Macacus rhesus*. In morphological features they resemble the forms found in smears and sections of the ticks, yet their presence had no relation to infectivity. Immunologically they are not related to the spotted fever virus. All three are pleomorphic under cultural conditions, and the question arises whether or not the minute non-pathogenic *Rickettsia* forms and the somewhat coarser symbionts found in *Dermacentor andersoni* are morphological variations due to variations in nutrition, oxygen tension, tissue reactions, &c., in the different tissues and cells in which the organisms are embedded. At all events, the differentiation of the non-pathogenic Rickettsia-like organisms from *Dermacentroxenus rickettsi* is extremely difficult. In definitely infective ticks intranuclear forms were not constant. A point of special interest is that these non-pathogenic micro-organisms from ticks grow best at room temperature, in this respect resembling culturally certain flagellates inhabiting the alimentary tract of insects. The difficulty of obtaining initial growth on artificial media and the gradual adaptation to less specialized media are notable characteristics of these organisms. The possibility that *B. rickettsiformis* is a non-pathogenic phase of the spotted fever organism, comparable with the avirulent flagellate culture forms of leishmanias, seems remote in view of the negative immunological findings. Hereditary transmission of *B. rickettsiformis* is clearly indicated by its presence in large numbers in ovaries and egg cells, a characteristic also of the spotted fever organism and of other insect-borne rickettsiæ.

Reviews.

A General Consideration of Snake Poisoning and Observations on Neo-tropical Pit-vipers By Afranio Do Amaral, of the Serum-Therapeutic Institute, Butantan, Brazil. Humphrey Milford, Oxford University Press. 10s. 6d.

A collection of reports of studies carried out in the Herpetological Laboratory of the Museum of Comparative Zoology, and in the Harvard School of Public Health. It consists of (*i*) a general review of snake poisoning, and (*ii*) a critical study of specific external characteristics of certain Brazilian pit-vipers.

The general review deals with the anatomy of the poison gland and the physical properties of the poison. Toxicity of a given poison appears to be most active on animals which are the natural food.

Little is known of the chemical composition of the toxins, generally considered to be a form of protein, but E. Faust claims to have separated a non-albuminous active principle in certain cases. Whatever the nature of the poison it appears to contain in varying degree substances which produce proteolysis, cytolysis and paralysis of the respiratory centre. A fibrin ferment is sometimes present, at others an antifibrin ferment. The specific action of the poison of various snakes is described.

Treatment of snake-bite. The serum treatment is the sole means of neutralizing the poison and arresting the noxious action which the several toxic elements exercise on body tissue.

Serum treatment, to be highly efficient, should be specific, but the Butantan Institute has produced a polyvalent anti-ophidic-serum. Emphasis is laid on the necessity for intelligent administration of serum. If properly prepared and well administered fatal accidents should be rare.

The remaining papers are purely zoological. The external characteristics of certain Brazilian pit-vipers are critically described. These are well illustrated with several excellently got up plates.

Medical News.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

(Division of Tropical Medicine and Hygiene)

Examination Result 80th *Session*, *March-July*, 1926.

Passed with Distinction: R. Crawford (winner of "Duncan" and "Lalcaca" Medals), E. G. Sayers, J. C. Paisley, I. G. MacGregor, W. Thomson, R. W. Thomas, T. C. Wakefield, R. B. Jackson, K. A. MacKay, J. A. W. Ebden, A. F. Babonau, E. Le Clezio.

Passed: D. S. Adkins, E. M. Clow, B. G. Wheatley, H. M. O. Lester, A. Schourenkoff, P. Milne, C. L. Digby Roberts, B. E. Ebden, W. S. Urquhart, M. K. Murray, V. A. Stookes, C. C. Taffs, I. Magdi, I. T. Kunaratnam, G. Sanders, G. C. Bergman, A. J. Boase, J. McNabb, V. J. G. MacGregor, W. Yuen, M. D. Macqueen, W. D. Pollard, D. I. Gracey, H. J. F. Wood, J. E. Chow, M. Din, A. J. Lee, G. W. Mearns, J. E. Howard, J. H. McDonald, A. M. K. O'Halloran, D. D. N. Selvadurai, A. Brooks, J. Symington, B. Merrin, C. Kearney, N. G. Rodriguez, B. Chiostri.

Dr. A. T. Stanton has been appointed Chief Medical Adviser to the Secretary of State for the Colonies.

THE JOURNAL OF

Tropical Medicine and Hygiene

AUGUST 16, 1926.

SPECIAL CANCER NUMBER

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed to the Editors.

4.—All **business communications** and **payments**, either of subscriptions or advertisements, should be sent to the Publishers of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum**, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 " "	1	3	3
200 " "	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 " " "	2	6	0
200 " " "	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

OBSERVATIONS AND RESEARCHES ON THE EPIDEMIOLOGY OF CANCER MADE IN HOLLAND AND ITALY (MAY-SEPTEMBER, 1925).

By LOUIS WESTENRA SAMBON, M.D.

(*Lecturer in the London School of Hygiene and Tropical Medicine*).[1]

THANKS to the strong and continued support given me by the "Tropical Disease Prevention Association," I was able to continue my researches on the epidemiology of cancer in Holland and Italy, during the spring, summer and autumn of 1925.

During the Italian expedition, I had the honour of being accompanied and assisted in my researches by Dr. H. A. Baylis, M.A., D.Sc., Helminthologist; Mr. K. G. Blair, B.Sc., Entomologist, and Mr. J. Ramsbottom, O.B.E., M.A., Mycologist, all three of the British Museum (Natural History); by Dr. C. Bonne, Director of the Antoni van Leeuwenhoek-Huis Laboratory (Dutch Cancer Institute), Amsterdam; by Dr. A. Ciurcentaler, retired Chief Medical Officer of the Trentino, Italy; by Dr. T. C. Pan, a graduate of the London School of Hygiene and Tropical Medicine, and by my daughter, Miss J. Sambon, a temporary Preparator in the Zoological Department of the British Museum (Natural History).

During our stay in Italy, Professor F. Hobday, C.M.G., F.R.C.V.S., F.R.S.E., joined us and helped us in our work for a short period, while Dr. A. Leslie Sheather, M.R.C.V.S., and Dr. W. H. Andrews, M.R.C.V.S., helped us in our experiments at home.

Financed by a grant received from the British Empire Cancer Campaign, we worked in the Trentino, Italy, during the months of July, August and September. We are now continuing our laboratory researches at home with material brought back from Italy.

In Italy, the Commission received every possible assistance from the Italian Government, the Local Authorities, and the District Medical and Veterinary Officers. Particularly are we indebted to Dr. E. Weiss, Chief Medical Officer of the Province of Trento; to Dr. Bezzi, Director, and Dr. Giuseppe Gilli, Chief Surgeon of the Municipal Hospital of Trento; to Commendatore Giulio Catoni, Director of the Provincial Agricultural Institute of Trento; to Dr. Pierandrei, Superintendent of the Municipal Abattoir of Trento; and to Dr. Enrico Scrinzi, Communal Medical Officer of Villa Lagarina.

To this report of the recent Italian investigations I propose to add a very brief preliminary account of the researches I made in North Holland, Friesland and Zeeland last Spring, together with Dr. Bonne, of the Dutch Cancer Institute; Dr. J. van Dam, of Rauwerd, in Friesland; Dr. C. Bakker, of Broek, in Waterland; Dr. Vieugels Schutter, of

[1] Report submitted to the Committee of the Tropical Disease Prevention Association, December, 1925; printed and submitted to British Empire Cancer Campaign, January, 1926. Authorization to publish obtained July 20, 1926.

FIG. 1.—Villa Lagarina.

Oosterland, in the Island of Schouwen-Duiveland, and others.

The object of these expeditions was to continue and extend researches on the epidemiology and ætiology of cancer made in Italy in 1924 with the help of a grant received from the British Empire Cancer Campaign; also in Iceland and Italy, in the autumn of the same year, with financial assistance received from the Tropical Disease Prevention Association and from personal friends.

The Italian researches of 1924 led to the discovery that in the village of Villa Lagarina, near Rovereto, in the valley of the Adige, during the last half century, cancer had been prevalent, but limited in incidence to one section of the village and more par-

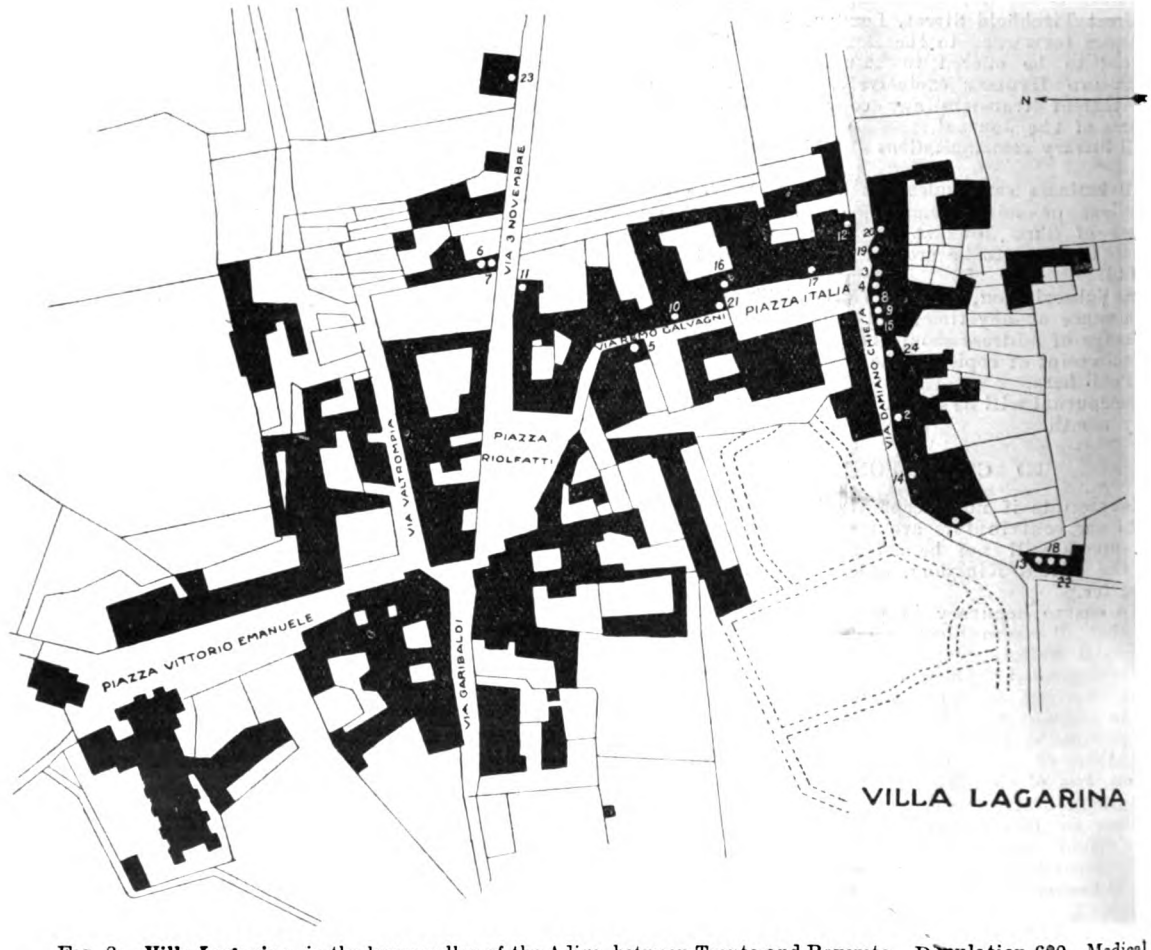


FIG. 2.—**Villa Lagarina**, in the lower valley of the Adige, between Trento and Rovereto. Population 680. Medical Officer of Health: Dr. Enrico Scrinzi.[1] During last 42 years (1884-1925), 24 cancer cases (11 males, 13 females). Distribution striking. Disease limited to one section of village. Via Damiano Chiesa and immediate neighbourhood particularly affected. One house, 5 cases, another, 3.

Year of decease, sex and age of cases in chronological order: (**1**) 1884, M., 60; (**2**) 1884, F., 58; (**3**) 1884, F., 76; (**4**) 1885, F., 77; (**5**) 1885, F., 81; (**6**) 1885, M., 78; (**7**) 1891, F., 71; (**8**) 1892, F., 70; (**9**) 1893, F., 57; (**10**) 1893, F., 67; (**11**) 1897, F., 50; (**12**) 1905, F., 67; (**13**) 1909, M., 73; (**14**) 1911, M., 64; (**15**) 1912, F., 63; (**16**) 1915, M., 76; (**17**) 1917, M., 62; (**18**) 1920, M., 50; (**19**) 1922, M., 77; (**20**) 1923, M., 72; (**21**) 1924, F., 56; (**22**) 1924, M., 58; (**23**) 1924, F., 55; (**24**) 1925, M., 49.

Visceral location of tumour: Stomach, 17 (1, 3, 4, 5, 6, 7, 8, 10, 11, 12, 13, 14, 17, 18, 19, 21, 22); oral cavity, 3 (16, 20, 23); breast, 2 (9, 15); site not mentioned, 2 (2 carcinoma, 24 sarcoma).

Relationship: 8, 9 and 15 sisters, also nieces of sisters 3 and 4; 24 nephew of 11 and 21; 18 and 22 brothers, also grand nephews of 1.

At the time of our visit there were no known cases of cancer in Villa Lagarina. The nearest case was one of the breast in the adjoining hamlet of Pederzano (see fig. 3).

[1] Black patches on this map and following represent blocks of houses.

ticularly to the Via Damiano Chiesa. This striking restriction of the disease, of which we had definite information, demanded careful investigation, especially as it was neither unique nor fortuitous, but repeated, though not so strikingly, in several towns and villages of Italy and other countries.

Such limitations, as well as sundry peculiarities noticed in the topographical distribution, visceral location, seasonal incidence, and periodic fluctuation of cancer, were incompatible with the prevailing ætiological theories which ascribed the disease to certain foods, beverages or drugs, to lack or excess of vitamines, to heredity, embryonic remains, endocrine disturbances, to constipation, or to civilization.

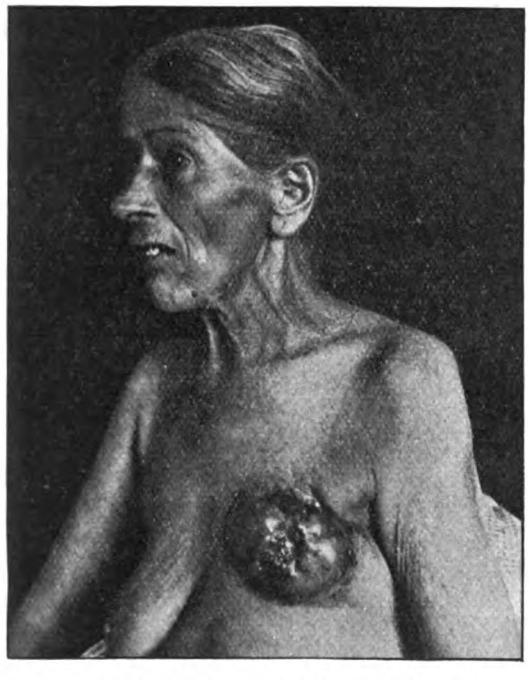

FIG. 3.—Case of breast carcinoma from Pederzano, near Villa Lagarina.

They forcibly suggested an infection of specific nature, probably dependent for its transmission and development on intermediary agencies with like distribution and, if animate, with correlative bionomics. Therefore I proposed making, in Villa Lagarina and other suitable villages, a comparative study of the flora and fauna of houses with and without cancer cases, in order to find out whether household pests such as fungi, cockroaches, cellar-beetles, meal-worms, bed-bugs, rats or mice were present, and whether they played any part in the incidence of the disease, or if any parasites, fostered by house vermin, might be concerned.

Further, on account of Erwin Smith's important researches on " crown-gall " in plants, the discovery of *Bacterium tumefaciens* in man by Friedmann and Magnus, as well as the recent experiments of Blumenthal, who claims to have produced malignant growths in animals by the inoculation of the crown-gall virus, I decided to make inquiries into the distribution and prevalence of crown-gall in the districts visited.

EPIDEMIOLOGICAL RESEARCHES.

The writing up of the epidemiological part of our work, to which I attach considerable importance, will require some time owing to the amount of statistical data that have to be collated and carefully verified and, further, on account of the several maps and diagrams which have to be prepared and cannot be completed, until all necessary data are at hand and have been satisfactorily checked. Dr. Ciurcentaler is continuing to help us in this arduous work with great zeal and proficiency.

A considerable amount of our time was devoted to the verification of data in Villa Lagarina, S. Michele of Appiano, Lavis, Lases, Mezzana, Mezolombardo, as well as other villages which presented a more or less obvious localization in the incidence of cancer.

I am glad to be able to affirm that our data have been subjected to the close, reiterated reading of death registers, the repeated inspection of localities and houses affected, the examination of cancer patients, and to the pertinent inquiries made at the residences of people who had died of cancer, by Dr. Ciurcentaler and myself with the aid of local authorities, physicians, and village-elders. During part of the time we were joined in this work by Dr. Bonne and other members of the Commission.

We were particularly anxious to ascertain, so far as possible, the perfect exactness of the data supplied by the local health officers and already in part verified by Dr. Ciurcentaler. This attitude of meticulous care was taken in order to establish, as firmly as possible, the truth of localism and other peculiarities of distribution which, if real, should prove not only of epidemiological interest, but of great value in the elucidation of the ætiology of cancer.

For each fact of special interest in town, village, or hamlet, I now hold official documents duly stamped and signed by the local mayor, ecclesiastical authority, district or communal medical officer and municipal secretary.

The value of statistics is always relative, and, personally, I am particularly sceptical about cancer statistics as now collected and " corrected," but in a small community such as Villa Lagarina, where there are two very capable native physicians, one, the father, with a local experience of over forty years, the other, the son, fully versed in the methods of modern medicine, there can be no great risk of error. Besides, Villa Lagarina is at a short distance from Trento and Rovereto, therefore its cancer cases are sent for operative or X-ray treatment to either of these towns, both of which possess well-equipped hospitals and excellent surgeons. Trento, moreover, has a young pathologist competent to make the necessary histological examinations.

In distant out-of-the-way places, more especially in the case of old data registered by physicians long dead, or by a priest or municipal secretary, the official figures can have but little value. Then, again, until quite recently, the diagnosis of cancer often was masked by denominations such as " stomach degeneration," or " senile degeneration," so, at times,

it was a difficult question for us to decide whether some of these " degeneration " cases should be regarded as cases of genuine cancer.

Though necessarily obliged to postpone for a while the complete publication of our epidemiological researches with accompanying maps, diagrams and figure-tables, I beg to submit very briefly some of the more interesting facts gleaned through my recent investigations in the Netherlands and Italy.

The recent researches have fully confirmed my previous findings and brought out in the clearest possible way that:

(1) Cancer distribution and prevalence vary from place to place, often considerably, irrespective of climate, race, food, type of dwelling, habits and customs.

I have seen cancer—indubitable cancer—in the north of Iceland, almost within the Arctic Circle,

FIG. 4.—View of the upper valley of the Adige.

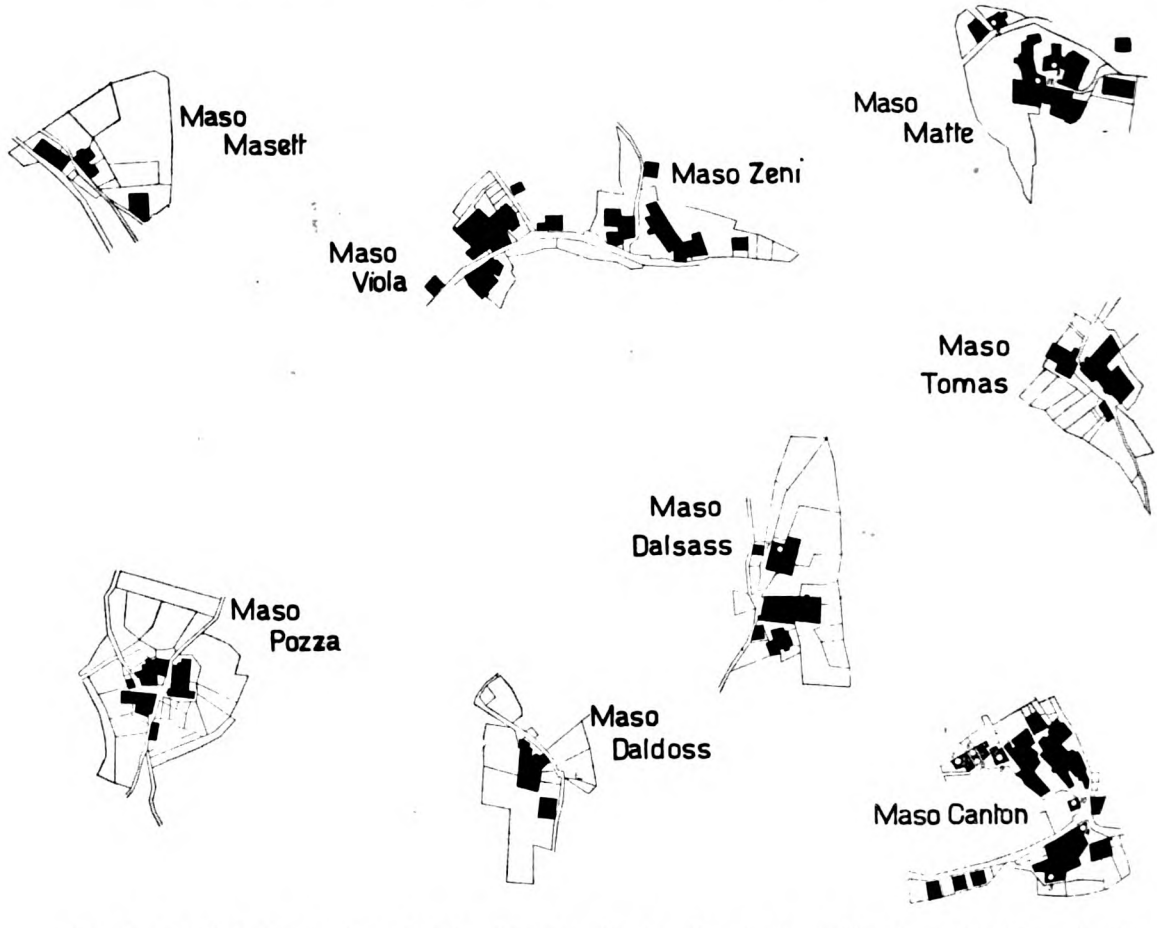

FIG. 5.—**Cavedago**, in the valley of the Non (about 9 miles from Mezolombardo, Trentino. Population 878. This Commune consists of twelve " frazioni " (sub-divisions) or hamlets scattered over the slope of Mount Cavedago, within a radius of less than 1½ mile. (*Only 9 hamlets shown on map.*)

Within the last 42 years (1884-1925) 11 cancer cases (5 males, 6 females) occurred, but they were limited to the three hamlets of Canton, Sass and Matte, the other nine, so far as known, always have been immune. Canton (population 278), 7 cases; Matte (population 136), 3 cases; Dalsass (population 79), 1 case.

Year of decease, sex and age of cases in chronological order: (**1**) 1890, F., 55; (**2**) 1897, M., 65: (**3**) 1898, F., 54; (**4**) 1900, F., 52; (**5**) 1902, M., 67; (**6**) 1907, M., 56; (**7**) 1914, M., 64; (**8**) 1915, F., 56; (**9**) 1917, M., 76; (**10**) 1918, F., 78; (**11**) 1924, F., 77.

Visceral location of tumour: Stomach, 4 (2, 6, 9, 10); œsophagus, 1 (7); larynx, 1 (11); rectum, 1 (3); uterus, 1 (8); location not indicated, 3 (1, 4, 5).

and in the Islands of Trinidad and Grenada, in the Torrid Zone, twelve degrees below the Tropic of Cancer. I have seen it in Dutch villages situated on reclaimed land, actually below sea level, and in Italian hamlets perched at glacier heights on the Eastern Alps. I have seen it in filthy hovels with offensive dung-pits digged at the very door, as well as in the gaily painted, highly-polished and spotless cottages of Broek, a quaint Dutch burgh noted for its exquisite cleanliness. I have found it among the fish-eaters of northern islands, the meat-eaters of merry England, and the vegetarians of Italy and the West Indies; I have found it among low-ground wine-bibbers and mountain milk-drinkers. Yet, everywhere, even in districts covering the smallest area of plain, valley or mountain, one finds villages, or groups of houses totally or partly immune, by the side of others severely affected.

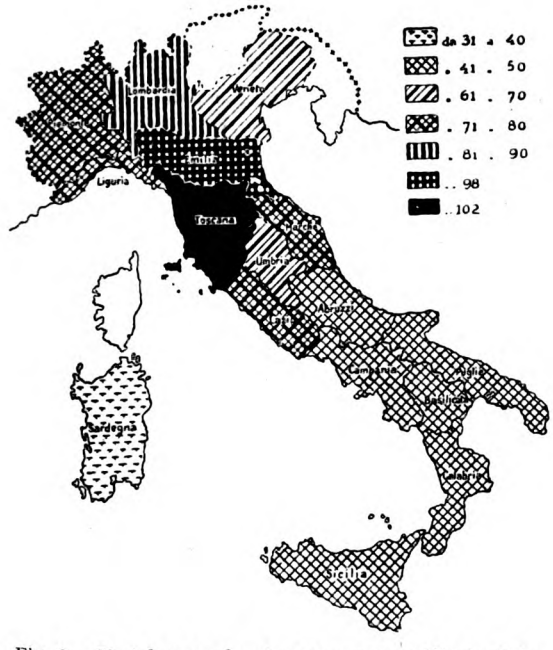

Fig. 6.—Sketch map showing cancer mortality in Italy, 1914-1918, pro 100,000 inhabitants.

To give an example, I might mention the district of Cavedago, in the Trentino. It consists of twelve "frazioni" (sub-divisions or outparts of a parish) or hamlets scattered about the slopes of Mount Cavedago. One of these, Canton, with 278 inhabitants, records seven deaths from cancer between 1885 and 1925; two others—Dalsass and Matte—have had only four cases between them during the same period of forty years, whilst the remaining nine are, and, so far as known, always have been, immune.

As Frederick L. Hoffman states in his valuable work on "The Mortality from Cancer Throughout the World": "The fact is incontrovertible that an enormous range in cancer frequency is met with throughout the world, and that as yet no generally accepted theory in explanation of such a wide degree of divergence has been advanced."

Striking inequalities in the topographical distribution of cancer have been noticed and reported again and again, yet, so far, they have not received the attention they deserve. Properly investigated they should inevitably lead to the elucidation of the ætiology of cancer.

(2) The organs, or parts of the body, more frequently affected by cancer vary, not only in countries far removed from one another, but also, and often strikingly, in adjoining districts.

No less striking than the great inequality in the geographical and topographical distribution of cancer is the diversity of its repartition by organ, or

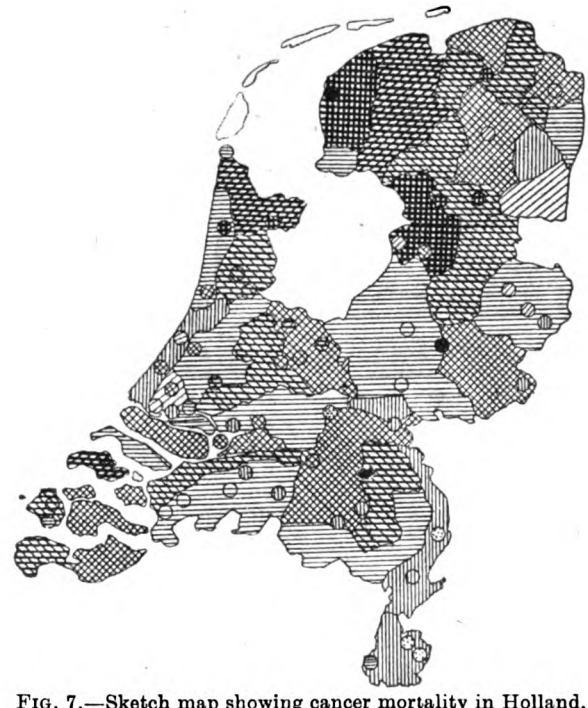

Fig. 7.—Sketch map showing cancer mortality in Holland, 1911-1915, pro 10,000 inhabitants.

part of body, in different countries and localities. Some of these differences are well known, such are the rarity of cancer of the female breast in Japan compared with its great frequency in England; the extraordinary frequency of penile cancer in certain parts of Asia, contrasting with its rarity in Europe and America; the great prevalence of primary hepatic cancer in certain coast-districts of Asia and its rarity in Europe; the commonness of cancer of the stomach in Europe, its rarity in Asia.

Differences in visceral location just as striking are found in different animals; such are the great frequency of mammary cancer in she-cat and bitch, its extreme rarity in the cow; the very common occurrence of cutaneous epithelioma in the dog,

its scarcity in stallion and bull; finally, the great rarity of cancer of the alimentary tract in animals as compared with its frequency in man.

(3) As a rule, cancer cases seem to be distributed in groups or clusters. A first case usually is followed by one, two, three or more cases, either in the same house, or in adjoining or neighbouring houses, the successive patients being sometimes related, more often not

This peculiar group distribution of cancer cases I have noticed repeatedly in Iceland, England, Holland and Italy.

In Holland, Dr. H. T. Deelman already had published in 1920 a very interesting work on the main distribution of cancer in the Netherlands, based on carefully collected and expertly handled statistical data, while a Friesian country doctor, Dr. Jacob van Dam, had written a paper on the distribution of cancer in his own district—that of Rauwerderham—and in the district of Idaarderadeel which adjoins.

Dr. Deelman's maps show, at a glance, that the prevalence of cancer in the Netherlands is, as in every other country, most unequal. Dr. van Dam's work deals, not with lumped statistics, but with local data personally and most carefully collected. Therefore it is of the greatest possible value. If all district medical officers had done the like, the ætiology of cancer might be no mystery.

FIG. 8.—Village of Rauwerd, Holland. (Photo by Dr. C. Bonne.)

FIGS. 9 and 10.—**Vermiglio,** near Tonale Pass, Trentino. Medical Officer of Health: Dr. Paolo Melchiori.

Distribution.—The characteristic group distribution of cancer is well exemplified in Cortina and Fraviano, two "frazioni" or divisions of the Commune of Vermiglio.

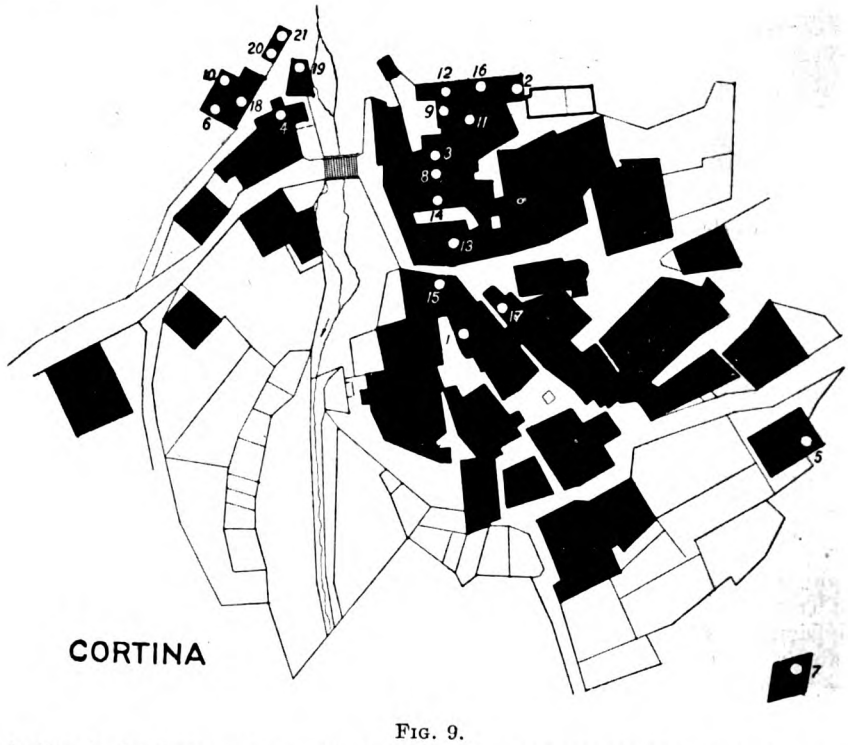

FIG. 9.

Cortina.—Cortina is the larger "frazione." During the last 42 years (1884-1925) 21 cancer cases (12 males, 9 females). According to Dr. Melchiori, the disease started in two houses placed, almost opposite, one on each side of the Cortina stream. Since 1885, these houses presented, one 4, the other 3 cases, in persons more or less related.

Year of decease, sex and age of cases in chronological order.—(**1**) 1885, M., 60; (**2**) 1886, F., 63; (**3**) 1886, F., 64; (**4**) 1900, M., 55; (**5**) 1901, F., 49; (**6**) 1902, M., 74; (**7**) 1903, F., 53; (**8**) 1906, F., 54; (**9**) 1907, F., 71; (**10**) 1908, M., 47; (**11**) 1912, M., 81; (**12**) 1912, M., 66; (**13**) 1914, M., 52; (**14**) 1915, F., 58; (**15**) 1916, M., 56; (**16**) 1916, M., 60; (**17**) 1918, M. 57; (**18**) 1923, M., 57; (**19**) 1925, M., 49; (**20**) —, M., 74; (**21**) — F., ?.

Visceral location of tumour: Stomach, 13 (1, 6, 7, 10, 11, 12, 13, 14, 15, 17, 18, 19, 20); liver, 2 (4, 16), sigmoid flexure, 1 (9); breast, 1 (3); uterus, 2 (5, 21); face, 1 (8); ovary, 1 (2).

Relationship: 12 brother of 6; 8 and 14 sisters; 10 nephew of 8 and 14; 10 nephew of 6; 17 cousin of 8 and 14; 11 husband of 9 and 21 wife of 20.

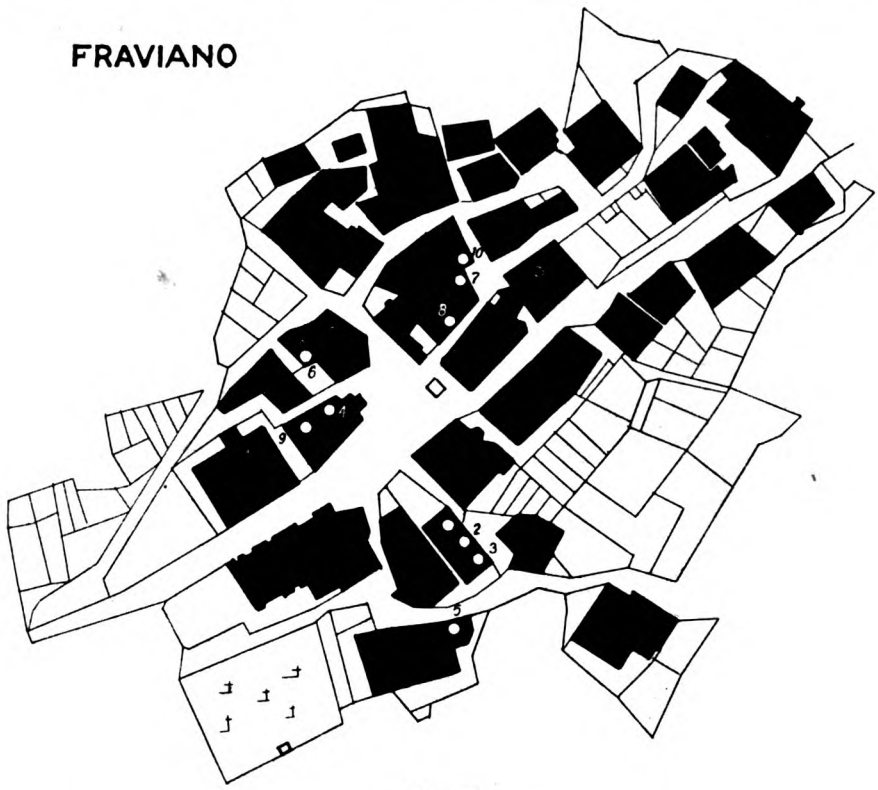

FIG. 10.

Fraviano.—During same period of 42 years 10 cancer cases (3 males, 7 females).
Year of decease, sex and age: (1) 1889, F., 75; (2) 1895, M., 60: (3) 1896, M., 53; (4) 1904, M., 26; (5) 1908, F., 52; (6) 1909 F., 43; (7) 1917, F., 53; (8) 1924, F., 68; (9) 1925, F., 53; (10) 1925, F., 76.
Visceral location of tumour: Stomach, 5 (2, 3, 5, 8, 9); rectum, 1 (10); breast 3 (1, 6, 7); sarcoma, 1 (4).
Relationship: 2 and 3 brothers; others not related.

Already at Broek, in Waterland, Dr. Bonne and I were able to recognize this characteristic clustering of cases, but in the village of Zuiderwoude, and in Friesland, in the villages of Rauwerd, Terzool and Sijbrandaburen, the grouping was unmistakable, though perhaps not so marked as in certain Italian villages such as Villa Lagarina, Lavis, Lases, Mezzana, Mezolombardo, San Lorenzo, S. Michele, Rovere di Luna, Vermiglio, and others.

The relationship of cases, in each group, becomes still more evident when we consider the date of each successive case, its connection with other cases, and the organ or part of the body affected.

FIG. 11.—Group of "cancer houses" at S. Lorenzo, in Pusteria.

At S. Lorenzo, in Pusteria, Dr. Hermann Steger took us to see a striking group of "cancer houses" in "frazione" Pflaurenz. It consisted of five buildings: No. 3, an inn, named "Locanda al Pescatore," kept by the family Kofler, in which during recent years four cases of cancer had occurred; No. 4, an adjoining house, also with four cancer cases; No. 5, contiguous to No. 4, with three cases; No. 2, a detached house, with one case, and No. 23, just opposite the inn, with one case.

(4) Often, in a cancer cluster, all, or the majority of the patients, whether related or not, are affected in the same organ, or in the same part of the body.

In my second cancer report (JOURNAL OF TROPICAL MEDICINE, February 2, 1925) I drew attention to the fact that frequently in non-related people inhabiting the same house, or adjoining, or neighbouring houses, one came across two, three, or more persons suffering from the same type of neoplasm usually affecting the same organ, or the same part of the body. I pointed out that, whilst the homotypic transmission of cancer in successive generations of a single family might lead one to consider the theory of hereditary

FIG. 12.—**Mezzana** in Val di Sole, Trentino. Population 950. Medical Officer of Health : Dr. Attilio Gallina. During last 42 years (1884-1925) 42 cancer cases (22 males, 20 females).

Distribution.—Cases appear somewhat scattered, yet cluster distribution is evident, especially when one takes into account changes of habitation as in Cases 11 and 13, who first lived in the house inhabited by Case 1. The various clusters show no evidence of hereditary transmission.

Year of decease, sex and age of cases in chronological order :—(**1**) 1885, M., 55 ; (**2**) 1886, M., 71 ; (**3**) 1886, F., 67 ; (**4**) 1887, F., 43 ; (**5**) 1887, F., 58 ; (**6**) 1887, M., 55 ; (**7**) 1889, F., 60 ; (**8**) 1892, F., 60 ; (**9**) 1892, F., 62 ; (**10**) 1892, F., 65 ; (**11**) 1895, M., 66 ; (**12**) 1897, F., 58 ; (**13**) 1898, M., 69 ; (**14**) 1899, F., ? ; (**15**) 1900, M., 82 ; (**16**) 1902, M., 46 ; (**17**) 1903, F., 43 ; (**18**) 1903, F., 74 ; (**19**) 1907, M., 76 ; (**20**) 1908, M., 82 ; (**21**) 1908, F., 69 ; (**22**) 1911, M., 60 ; (**23**) 1912, F., 45 ; (**24**) 1914, M., 83 ; (**25**) 1915, M., 51 ; (**26**) 1916, F., 72 ; (**27**) 1916, F., 50 ; (**28**) 1916, F., 60 ; (**29**) 1917, M., 62 ; (**30**) 1918, F., 69 : (**31**) 1918, M., 69 ; (**32**) 1919, M., 53 ; (**33**) 1920, M., ? ; (**34**) 1920, M., 61 ; (**35**) 1920, M., 67 ; (**36**) 1922, M., 58 ; (**37**) 1922, F., 48 ; (**38**) 1923, M., 56 ; (**39**) 1923, F., 35 ; (**40**) 1924, F., 66 ; (**41**) 1925, M., 66 ; (**42**) 1925, M., 69.

Visceral location of tumour :—Stomach, 18 (2, 6, 7, 11, 13, 16, 17, 18, 24, 25, 26, 29, 30, 31, 36, 38, 41, 42) ; œsophagus, 1 (22) ; intestine, 4 (34, 35, 39, 40) ; rectum 1 (33) ; peritoneum, 1 (32) ; abdomen, 3 (5, 8, 9) ; thyroid, 2 (10, 27) ; liver or stomach and liver, 4 (12, 20, 21, 28) ; face, 1 (3) ; breast, 2 (23, 4) ; uterus, 1 (37) site not stated, 4 (1, 14, 15, 19).

Relationship.—Only one instance of cancer in parent and progeny : a case not of mother, but of father (11) and son (36). Six and 13 were brothers ; 4 and 41 cousins ; 23 niece of 2 ; 42 niece of 37 ; 33 nephew of 31. Cancer in people related by marriage and living in the same house are frequent : 7 wife of 1 ; 24 husband of 5 ; 17 daughter-in-law of 10 ; 27 daughter-in-law of 15 ; 23 daughter-in-law of 20 ; 3 and 18 sisters-in-law, so also 40 and 41. Still more frequent are the cases of cancer in total strangers inhabiting the same house. In one house we find 4 cases : owner (24), his wife (5) and two non-related lodgers (29 and 38) ; in another, 3 cases (12,25, 34) all non-related.

transmission plausible, this theory could not explain the occurrence of cancer of the same type and location in persons of different stock inhabiting the same house, or in total strangers occupying neighbouring houses. I gave an interesting instance of three cases of cancer of the throat (one of tonsils and pharynx and two of larynx) at Caldaro, " frazione " Mezzavilla, in non-related persons one of whom was only thirty-two years of age when he died. They had been attended by Dr. Carl Konzert, the local health-officer.

Similar cases have been described in medical literature from time to time. Thus, in 1903, in the *Lancet*, Dr. W. Gifford Nash reported a group of five cases, three of which died from cancer of the tongue in one village (North Bedfordshire) within the space of sixteen days.

During our recent investigations we have come across further examples of the kind. For instance, Dr. F. Pizzini, health-officer of Rovere di Luna, stated that five cases had occurred in his district between 1913 and 1925. Of these, four were females belonging to different families and living in different but neighbouring houses: one of them had cancer of the uterus, the other three died of cancer of the breast, an incidence somewhat rare in those parts of the Trentino visited by us. At S. Michele, the local health-officer reported two cases of bladder cancer in the same house: the patients were cousins. In Holland and Italy I have often noticed the appearance of several cases of hepatic cancer in close proximity. Cancer of the liver is very common in many tropical countries, but in Europe it is generally looked upon as secondary to cancer of the stomach and, no doubt, in the majority of cases it is so. However, primary cancer of the liver has been observed in East Prussia (Kurisches Haff) and in Hungary (Kolozsvar). Its presence among the fisher-folk of the Kurisches Haff has been ascribed by Askanazy, Rindfleisch and others to the parasitism of *Opisthorchis felineus*, a

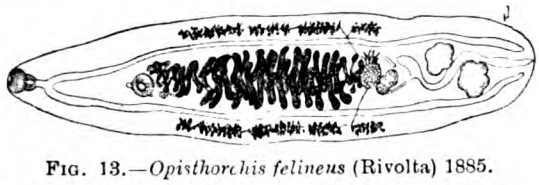

FIG. 13.—*Opisthorchis felineus* (Rivolta) 1885.

tiny liver fluke described in 1885 by Rivolta, who found it in dogs and cats in Italy. I have no longer any doubt as to the occurrence of primary liver cases in certain parts of Italy, but have had no opportunity of studying their ætiology.

At Cesoino, a " frazione " of Pederzano, situated above Villa Lagarina, Dr. Scrinzi took me to see a woman—Elisa Candioli—seventy-six years of age—who had a ghastly rodent ulcer occupying the whole of the frontal region. The frontal bone had been destroyed, exposing the brain and its coverings. From beneath the ulcer's undermined edges fly-maggots (larvæ of *Lucilia*) dropped out with the ichorous, semi-purulent discharge. She had been well-nigh six years in this pitiable condition, but the disease had started long before as a scaly patch on the forehead. She lay moaning on her bed and complained of fearful restlessness at night and of lancinating pains and burning in her head. The stench from her open cancer was unbearable. The lymphatic glands were not perceptibly enlarged. Dr. Scrinzi cleansed and dressed the sore and the poor woman said, " At last I believe I have found someone who shall heal me. As soon as I am well again, I will go straight to Rome and kiss the feet of the Santo Padre."

In the house adjoining, another old woman—Santa Mancia—had died not long before of a similar skin epithelioma. Dr. Scrinzi had seen her and he told me that in her case the corrosive ulcer had started from beneath the right eye and had gradually spread down to the shoulder.

In Donna Candioli's house, we were informed that a cat had been destroyed on account of an extremely malodorous sore at the back of the head. A young girl, who had attended the patient and nursed the cat, presented on the face a peculiar skin disease which Dr. Scrinzi thought, on account of her age, might be lupus rather than a superficial variety of epithelioma.

In tuberculosis, cases of homotypic transmission to descendants had been looked upon, not only as evidence of hereditary transmission of the disease, but also as indicating the transmission of a particular susceptibility or predisposition of the organ affected (lung, kidney or skin, as the case might be). But, I believe, and laboratory experiments bear me out, that the selection of the organ has little to do with the host, but is made by the parasite, or, maybe, by some endogenous carrier and sower of the parasite, if there be one. It is certainly not a greater predisposition to disease that we inherit, but rather a greater resistance against it. Disease overcome, or battled against, in the parent, tends to produce immunity in the child. It is the parasite, nurtured in a certain organ, which invariably makes for that same organ in its successive transmissions to new hosts. The whole science of parasitology teems with proof of this. Therefore, to my mind, it is by infection alone that we can explain the very striking, but frequently occurring, fact of the homotypic transmission of cancer to persons of different stock inhabiting the same house or the immediate neighbourhood of a cancer focus.

(5) Notwithstanding occasional increase in certain localities, decline in others, the relative frequency of regional incidence shows, as a rule, the same remarkable persistence which is characteristic of the " stations " of well-known endemic diseases.

The researches of Moore, in 1865, and those of Haviland, a few years later, show, when compared with recent data, that for about a century, at least, cancer in England has maintained the same topographical distribution and exhibited the same relative prevalence. This is exactly what we find in Italy, Holland, Germany, and other countries.

(6) Notwithstanding general progressive increase or decline, cancer exhibits, in its local incidence, noticeable fluctuations from year to year, such as are witnessed in all endemic diseases.

As pointed out in my first cancer report (JOURNAL OF TROPICAL MEDICINE, June 2, 1924), periodic fluctuations in the incidence of cancer have been noticed in Italy by Professor Foa and by Drs. Testi and Galli.

(7) For a number of years cancer may prevail exclusively in one section of a region, town or village, then affect some other section of the same, whilst continuing, increasing, diminishing, or completely dying out in the section previously affected.

This shifting of the incidence or prevalence of cancer from one locality to another I have observed on several occasions in different countries. For instance, in Italy, at S. Michele on the Adige, a village of 850 inhabitants, we found that fourteen cases of cancer had occurred during the last forty years. For twenty-seven years (1892-1920), with the exception of a single case (see fig. 14, Case 1), at the extreme north end, the disease (Cases 2, 3, 4, 5, 6, 7, 8) had affected only the centre of the village, the cases occurring along the broadway in non-related persons belonging to different families. From 1920 onwards no further cases occurred in this area, the next six (9, 10, 11, 12, 13, 14) cropping up to the north-east of the central section. Case 9 (1920) sickened and died in the house adjoining that of Case 1 (1892), at the extreme north end of the village, but was in no way related; indeed, whilst Case 1 was an Italian, Case 9 was an Austrian. The only instance of family connection between any of the cancer cases in S. Michele was that of Case 10, who was a cousin of Case 13.

On consulting the map, one cannot help noticing the striking propinquity of cases with similar organ location. The three bladder cases (11, 12, 13), like the three uterine cases (3, 4, 8) and the two œsophageal cases (5, 6), are grouped or ranked in close vicinity and so are the stomach cases arranged in pairs.

The inhabitants of S. Michele are mostly well-to-do wine-growers, and the district around the village is a flourishing viticultural centre famous for its dark, rich Toroldic wine, much in request for giving body to lighter wines.

At Mezolombardo, a borough of about five thousand inhabitants and centre of the wine trade of a vast extent of grapeland, cancer first prevailed in the upper and middle portion named Cornel and in the subjacent section called Canovarie (cellarage), where, in days gone by, stood the Bishop's cellars, used to store the ecclesiastical tithes in wine, grain and other provisions, and where many of the inhabitants still bear the name of Kellner (cellarer). Thence the disease spread to right and left, each year more widely, reaching successively Contrada (1885), Piaz (1886), Villa (1890), Ospedale (1900) and even Borghetto (1891)—a group of houses, at

FIG. 14.—**S. Michele-on-Adige,** near Trento. Population, 850. Medical Officer of Health, Dr. Fausto Onestinghel.

During last 42 years (1884-1925) 14 cancer cases (7 males, 7 females). Distribution striking. For 27 years (1892-1920), with exception of first case, at the extreme north end, the disease (cases 2, 3, 4, 5, 6, 7, 8) was confined to the centre of the village. From 1920 onwards, no further cases occurred in this area, the next six (9, 10, 11, 12, 13, 14) cropping up in the north-east of central section.

Year of decease, sex and age of cases in chronological order.—(**1**) 1892, M., age not mentioned; (**2**) 1893, F., 58; (3) 1899, F., 38; (**4**) 1906, F., 53; (**5**) 1911, M., 58; (**6**) 1916, M., 53; (**7**) 1919, F., 73; (**8**) 1919, F., 53; (**9**) 1920, F., 45; (**10**) 1920, M., 75; (**11**) 1921, M., 57; (**12**) 1922, M., 62; (**13**) 1924, F., 66; (**14**) 1924, M., 73.

Visceral location of tumour: Stomach 5 (2, 7, 9, 10, 14); œsophagus, 2 (5, 6); uterus, 3 (3, 4, 8); urinary bladder 3 (11, 12, 13), and 1 of general carcinosis (1).

Relationship: Only instance of family connection, 10 first cousin of 13.

the very end of the borough, where it long exacted heavy toll. Yet the disease continued all the while in the Cornel-Canovarie section where it seemed to have started.

The local health officer, Dr. Roberto Caprera, who had practised in Mezolombardo for nearly thirty years, told us that the prevalence of cancer had greatly declined in recent years. The last cases seen by him were two breast cases, both successfully operated, and one of cancer of the womb beyond surgical interference. In former years cancer was not only more frequent, but its visceral location seemed to be different. The organs more usually affected were the œsophagus, the stomach and the liver. During thirty years he had met with only three uterine cases, whilst in a single year (1907) he had examined three œsophageal cases. He never had seen cancer in husband and wife, nor in parent and progeny, nor, again, did he remember ever having seen more than one case in the same house, though he had noticed a certain grouping of cases in adjoining or neighbouring houses. The food of the people consisted chiefly of polenta (maize-mash) and vegetables, but they also ate a considerable amount of animal food and drank much wine.

Together with Drs. Caprera, Ciurcentaler and Pan, I visited the various sections of the borough, carefully inspecting houses in which cancer had occurred, and I paid special attention to the older Cornel-Canovarie section which is heaped up against the rocky, perpendicular side of Mount Fai. Here the houses are damp, ill-kept and noisome; they are seldom reached by the sun's rays, except for a short time in the early morning. At the very door of each house and right against the wall is a manure pit over which the latrine, projecting from the upper floor, discharges gargoyle-like. Hens and cockerels congregated on the dunghills to feast on the maggots. The houses swarmed with rats, mice and cockroaches (*Blatta orientalis* and *Blattella germanica*). Bedbugs and fleas were not unknown, as we soon discovered, notwithstanding Dr. Caprera's belief that they were prevented from breeding by the large amount of sulphur dust stored in the bedrooms against the powdery mildew (*Uncinula necator*) of the grape vine. Rheumatic fever was very common and just as prevalent in summer as during the spring and fall; it was invariably preceded by sore throat. Diphtheria was also common; sporadic cases cropped up every year, but epidemics did not occur now so frequently as formerly. Poultry, as a rule, suffered simultaneously with a like, or, may be, identical disease and Dr. Caprera told us that he had removed the characteristic false membranes from the birds' fauces.

In 1924, Dr. L. Nègre, of the Pasteur Institute, Paris, made some careful investigations on cancer epidemiology at Labastide-Rouairoux, on the River Toré, between Castres and Saint Pons, in the South of France, "to compare results with those obtained by Dr. Sambon in Romagna." He calls attention to the fact that, whilst cancer cases from 1900 to 1920 were equally divided between the two sections of Labastide, right and left of the river, from 1920 to 1923 the left side (Quartier du Galinel) had twice as many as the right.

Quite recently (1926) Dr. Himburg has drawn attention to an unusual increase of cancer in the village of Nörenberg, in Pomerania, Prussia. Nörenberg has about 2,600 inhabitants. During the years 1900-1913 cancer accounted for nearly 5 per cent. of all deaths, but between 1922 and 1924 the cancer mortality rose to 10 per cent. of all deaths, while in 1925 the percentage was still on the increase. This sudden augmentation is strikingly limited to the village of Nörenberg, contrasting with all neighbouring villages where cancer incidence has remained as it was. The mode of life and circumstances of the inhabitants of Nörenberg differ in no way from those of their neighbours.

(8) Cancer may break out suddenly in a place long immune, then disappear, or it may remain quiescent, at least in so far as man is concerned, for many years..

The village of Idaard, in the district of Rauwerderhem, Friesland, had presented unexpectedly six

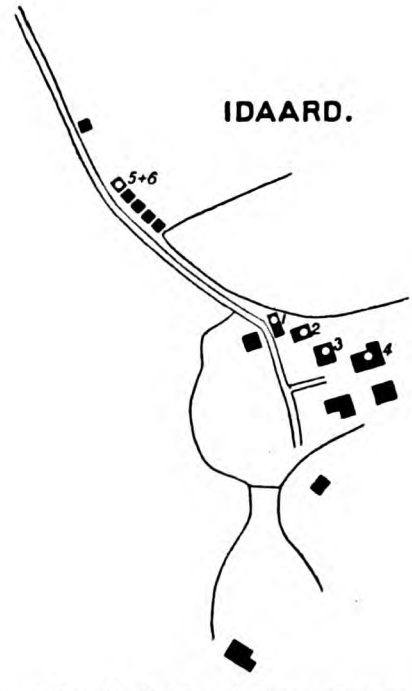

FIG. 15.—**Idaard,** district of Rauwerderhem, Friesland. Medical Officer of Health, Dr. J. van Dam.
This hamlet, at any rate since 1874, had remained immune from cancer; then, between 1912 and 1919, six cases occurred in persons (5 men and 1 woman) non-related.

cancer cases between 1912 and 1915, one each year in a group of adjoining houses. Two others in 1919 in a house at the north end of the village, then no more, as I was able to ascertain at the time of my visit in April, 1925. Prior to 1912 cancer never had occurred in Idaard, at any rate not since 1874, before which year there were no records.

The first Idaard case was one of œsophageal cancer in a shopkeeper who had succumbed to the disease in 1912, then a farmer died of gastric carcinoma in 1913, the third case was that of a teacher, who likewise had died of cancer of the stomach in 1914, and the fourth that of a clergyman, who had died of epithelioma of the face in 1915. All had lived for at least twenty-five years in the village; three of them were natives, whilst one, the teacher, had come originally from Leeuwarden. They were in no way related. The two cases reported in 1919 were: a man—a farm-hand—who had died of cancer of the stomach in October, 1919, and a woman—a housekeeper—who had come from elsewhere and had died of cancer of the vulva and vagina in July, 1919.

When Dr. Bonne and I visited Idaard together with Dr. van Dam, we examined the group of houses in which the first four cases had lived; they were the dwellings of well-to-do people, well-built, well-furnished, spotlessly clean and surrounded by pleasant gardens.

Whilst planning excursions in order to get a glimpse of cancer conditions in the Netherlands, Dr. Bonne told me that he had made arrangements for a trip to Vianen, a small fishing hamlet in the island of Schouwen, Duiveland, Zeeland, whence he showed me a letter received from one of his colleagues. The latter stated that whilst discussing my researches on the epidemiology of cancer, Dr. Vleugels Schutter of Oosterland, Zeeland, had told him that in the hamlet of Vianen, during the last twenty-five years, there had occurred about ten deaths from cancer, but not a single one from any other disease. This information certainly was remarkable.

On May 2, Dr. Bonne and I landed at Zijpe, in the island of Schouwen, where Dr. Schutter met us and drove us to his house in Oosterland. After luncheon we went to Vianen. Whilst driving there, Dr. Schutter told us his district was mainly agricultural; wheat, potatoes and the sugar-beet were the chief crops. The breeding of cattle was limited. There were numerous dogs and one or more cats in every house; rats abounded. Cancer was decidedly prevalent and the people feared it. The least ailment made them think they had the dread disease which some of them ascribed to the spraying of potatoes with Bordeaux mixture (copper sulphate and lime mixture).

We reached Vianen, a cluster of brick and wooden cottages standing on a dyke facing the Eastern Schelde. Behind us was a lakelet blue as heaven, and, beyond, green wheat-fields shimmering in the sunshine. The tide was out, leaving a vast smooth stretch of damp sand, flecked with bronzed seaweed, glittering pools and the silver wings of restless terns and gulls. A very old Dutchman, supporting the bowl of his pipe with a bony hand, was gazing over that pale arenaceous land, wishing, no doubt, that it might never again show as water.

Some of the cottages were ivy-mantled and their gardens hedged with clipped box. At the back were hen-coops and pig-sties and, behind all, the invariable ditch of foulest water. We entered one of the cottages; the walls within were of varnished wood and blue-painted tiles; it was scrupulously clean and tidy.

Along the road bright, red-cheeked children, with china-blue eyes and flaxen hair, ran, jumped, shouted for pure glee of existence, clattering upon their wooden clogs.

The inhabitants of Vianen numbered seventy, all told, and Dr. Schutter assured us that, during the last quarter of a century, there had been no deaths among them save from cancer. To be sure, two men had died of tuberculosis, but one was a total stranger who had died on arrival; the other, a student who had lived for some years in Utrecht, where he had contracted his illness. The Vianen cancer cases numbered nine (stomach 5, liver 1, intestine 1, abdomen 1, jaw 1) since 1900. During the last five years there had been no further cases of cancer and no deaths from any other disease. If one could but trust the dyke and wipe out cancer, there seems to be no reason why the good people of Vianen should not go on living for ever.

(9) Heredity does not seem to be a determining factor.

In his book on "Heredity," Professor J. Arthur Thomson, espousing the theory of "embryonic rests," makes a strange suggestion. He says: "Leaving microbic and acquired diseases out of account, we may safely say that various processes of hypertrophy which are associated with disease in a well-finished organism like man are, as it were, recrudescences of important steps in past evolution. The persistence of germinal activity in a patch of cells may give rise to a tumour, but is it not, as it were, an echo of the power that lower animals have of regenerating lost parts?"

Several laboratory investigators, such as Dr. Leo Loeb, Miss Maud Slye and others, have asserted that in mice there is not only a predisposition to develop cancer definitely hereditary, but that the hereditary transmission of the disease takes place in the true Mendelian manner, and Professor Powell White has even suggested that Dr. Gye has cultivated Mendelian factors *in vitro*.

In the field, studying men, not mice, I have seen nothing of the kind.

Besides, I cannot conceive the hereditary transmission of disease any more than that of mutilations such as circumcision, ear-piercing, ear-cropping, tail-docking which, like the pruning of trees, have been performed for countless generations without ever appearing in the progeny. What we do inherit is not the disease, but a greater power of resistance to it; not the mutilation, but a greater power of repair.

Hereditary traits and characters are said to lie within the chromosomes of the reproductive elements, but, so far, none of the disease-agents known to us has ever been located in the nuclear substance of the germ-cells.

It is true that in Arthropods certain disease-agents do pass from the infected mother to her offspring

through the egg, but in such cases the pathogenic organism is contained in the food-yolk, where it assumes a resting condition and awaits the development of the embryo, which it then attacks. Clearly, such cases are those of infection, not inheritance. Well-known examples are the "hereditary" transmission of *Nosema bombycis*, a microsporidium giving rise to the fatal pébrin disease in the caterpillars of the Chinese silk moth (*Bombyx mori*), and the transmission of *Babesia bigemina*, the cause of cattle hæmoglobinuric fever, effected within its tick vectors. In the latter case the pathogenic organism passes from the adult female tick, gorged on the blood of the diseased vertebrate, to its progeny, which in due time will convey it to a new bovine host. The parasite enters the tick's egg either in the ovary, or during its passage down the oviduct; later it invades the larva, finally reaching the salivary glands when the tick of the second generation, either as nymph or imago, becomes capable of transmitting the infection.

Physicians usually confound heredity with antenatal acquirement. Supposed cases of hereditary transmission in syphilis often are due to contamination of the offspring during transit through the maternal passages at birth, yet infection may occur *in utero* from mother to offspring during the period of gestation, because *Treponema pallidum*, like the trypanosome and other slender and very motile organisms, is able to traverse the placental filter. But the offspring of a syphilitic mother usually dies during fœtal life or soon after birth; rarely it grows, apparently healthy, to succumb to the disease at puberty or senescence.

Since the discovery of its specific germ, tuberculosis is no longer considered hereditary, yet the majority of physicians still hold that one may inherit some kind of "tendency" to tuberculosis. Such a conception which might seem reasonable in a community with high tubercular incidence, is contradicted by the greater susceptibility to the disease in members of non-tubercular communities when the latter, leaving their healthy surroundings, come in touch with tuberculous infection. There is no proof of any specific predisposition, all that can be reasonably maintained is a general constitutional debility favouring any kind of disease, and brought about by ill-nourishment during gestation.

In the case of leprosy, long considered a hereditary disease, it has been proved that the children of lepers, born out of leper districts, never inherit this malady.

At one time helminthic infestations were believed to be hereditary, and indeed the larvæ of certain worms may traverse the placenta and cord.

Reappearance of a disease in successive generations does not constitute inheritance. It is in the environment of members of the same family, brought up in the same locality and subject to the same conditions of life, that we must needs look for the explanation.

During my investigations in Italy and Holland I found that cancer might appear first in the children and later, sometimes much later, in the parents, or almost simultaneously in both. In 1887, in the *British Medical Journal*, Dr. A. Roper reported a case in which husband and wife had no trace of cancer in the history of their families and six of their children died of cancer.

Dr. van Dam, who had made a careful study of the heredity question in his district (Rauwerderhem, Holland), told me that in thirteen cases in which both parents had died of cancer their children were free, notwithstanding that, with few exceptions, all had reached the cancer age.

(10) The habitation of certain premises appears to be a factor of importance, at least whilst as yet undetermined cancer conditions persist.

Cancer in husband and wife was observed in Italy and Holland just as frequently as in England, France and other countries. At other times the primary case was followed by malignant disease in members of the same household, not necessarily in a blood relative or spouse, but in a brother-in-law, or in a sister-in-law, in a step-son or step-daughter, in a maidservant, a lodger, or, maybe, in a cat or dog.

At Coredo, an Alpine village of about a thousand inhabitants, situated on Mount Roen 830 metres above sea level, Dr. Cav. Luigi Ioris, the district medical officer, showed us a so-called "cancer house," now uninhabited, which had belonged to Dr. Luigi Ossana, a local physician, who had died in 1870 from

FIG. 16.—Dr. Ossana's house at Coredo.

intestinal cancer at the age of seventy-five. His death had been followed by the death of his wife, his two sons and his son-in-law, all of whom had lived in the same house and had succumbed to the same disease. The two sons had died, the elder in 1900, at the age of sixty, from cancer of the œsophagus, the younger in 1904 from cancer of the thyroid, when forty-eight years old. The wife had died in 1890 from cancer of the pharynx and tonsils; she was seventy-three years old when she died, and had been married forty-three years. There had never been any cases in her family. The most instructive case was that of the son-in-law, Professor Bartolo Sicher, who had died of cancer of the stomach in 1880 when only thirty-eight years of age. For eight years this gentleman had lived in Dr. Ossana's house. There was no cancer history in his family. A brother and two sisters of Dr. Ossana are still living and well, though very old.

(11) Cancer in dog, cat, fowl, or other domestic animal occasionally may be found in association with cancer in man under the same roof, either preceding or following it.

In my first cancer report (JOURNAL OF TROPICAL MEDICINE, June 2, 1924) I mentioned a few examples of cancer in man preceded, or followed, by malignant tumours in animals. These cases, supplied by Drs. Testi, Galli, Lama, Ghetti, Fedeli, Zanotti and others, were, for the most part, somewhat vague. In Holland I obtained more definite information. First at Broek, in Waterland, together with Drs. Bonne and Bakker, I had the opportunity of examining an eight-years-old draught-dog with an anal tumour of three years standing which had reached the size of a large plum. The local veterinarian, Dr. J. F. de Gier, told us of this dog that lived in a small house, behind the tramway station, where his master had died of cancer four and a half years previously. Examination of the tumour by palpation led us to believe that it might be a fibroma, but the veterinarian removed it on the following day and sent it to the Cancer Institute in Amsterdam. Here Dr. Bonne made sections and found it to be an epithelial neoplasm, a growth termed either adenoma or carcinoma by veterinarians. It affects not the rectal glands proper, but a group of circum-anal glands which open at the margin of the anus, lie under the skin, and are probably of the nature of scent glands. The frequency of this form of cancer in dogs has been put down to injury caused by scraping of the anal region along the ground, so-called "sleigh-driving."

Dr. Parree, who was with us at the time we examined the Broek dog, said that he remembered seeing a dog with a conspicuous growth beneath one of the lower eyelids, in a house in Zuiderwoude where lived a cancer patient.

When in Harlingen, Dr. Bonne and I called on Dr. B. Bosch, who told us that in a house close to his own, in Noorderhaven Street, there was a widow, Mrs. H., fifty-two years of age, who had come from Usquert, a village in the province of Groningen, where she had lived until 1920. A Harlingen cat, adopted by this lady in her loneliness, developed a mammary tumour on the right side and was brought to him for operation. He removed the growth in November, 1921, but it recurred six months later, when it was again removed. The cat lived a year and a half longer, but became so very ill that it had to be destroyed. In April, 1924, Mrs. H. came herself to consult him for a lump in the right breast which she had noticed as early as January. She was operated upon within a few days, but, as in the case of her cat, the tumour recurred and was removed a second time in January, 1925.

I asked Dr. Bosch to find out whether there had been any cancer in his patient's family, or in the houses she had previously inhabited. On May 4, 1925, Dr. Bonne informed me that he had received a letter from Dr. Bosch in which the latter wrote: "My patient (the breast tumour in the house of the cat with a tumour) is now fifty-two years of age. She lived in the province of Groningen till she was forty-seven, and then five years in Harlingen, always in the same house: Noorderhaven 55. She had never any contact with other persons suffering from carcinoma, and there was no history of cancer in her own family. In her present house there has been no cancer during the last twenty-five years so far as known, but there have been cases in neighbouring houses."

On my return to England, a friend informed me that one of his relatives, a lady of about 40, residing at Warley Woods, Birmingham, had been operated upon quite recently for cancer of the breast. She had long cherished a thoroughbred Yorkshire terrier, a bitch 14 years old who had been a very good mouser. This dog had never had puppies, but had suffered much from milk trouble. Hard lumps having been noticed in her mammary glands, she was taken to a veterinary surgeon, who said the disease was not malignant. Later, however, the dog got worse and was brought to another veterinarian who advised that the animal should be destroyed since the disease was cancer and an operation certainly would be followed by recurrence in about two months' time. Soon after the lady suddenly discovered a small lump in her left breast and was operated upon without delay.

PARASITOLOGICAL RESEARCHES.

Because in previous reports I had discussed at some length the part played by certain helminths (*Cysticercus fasciolaris*, *Opisthorchis felineus*, *Schistosoma hæmatobium*, *Oxyuris vermicularis*, *Trichinella spiralis*, *Gongylonema neoplasticum*, &c.) in the ætiology of tumours, it was suggested that, in the course of my epidemiological investigations in the Trentino, I should endeavour to ascertain whether any parasitic worm, fostered by house-vermin during its earlier stages, might not later become a factor in the production of cancer in man, or in domestic animals, harbouring its adult forms.

Certainly, I had averred that there was cogent evidence to show that *Cysticercus fasciolaris* (the

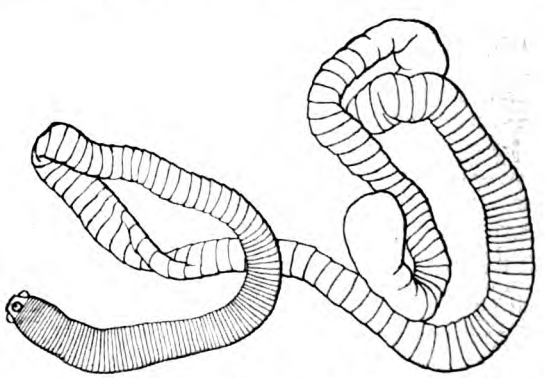

FIG. 17—Larval form of *Hydatigera tæniæformis* Batsch, 1786, usually spoken of as *Cysticercus fasciolaris*.

larval form of *Hydatigera tæniæformis*[1]) might bring about the development of sarcoma in the liver of infested rats, though I had not noticed any kind of growth in about eight hundred rats examined by myself at the London Docks. The majority of these rats had bladder-worms in their livers and in one the liver was so crammed with the strobilate larval forms of the cat's tape-like cestode, that the hepatic sub-

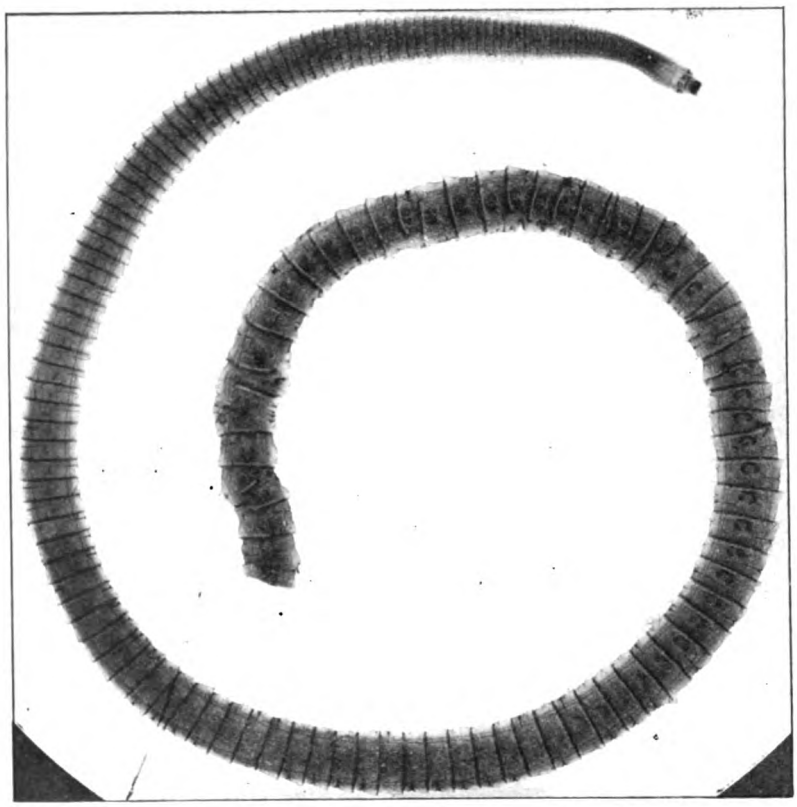

FIG. 18.—*Hydatigera tæniæformis*, Batsch, 1786.

[1] In my first Cancer Report (June, 1924), in mentioning Borrel's work on *Cysticercus fasciolaris* as a cause of hepatic sarcoma in rats and mice, I proposed *Reditænia* as a new genus of Cestoda, with *Tænia tæniæformis* of cats as type species, and I differentiated the larval stage, *Cysticercus fasciolaris*, from other cysticerci under the new name *Strobilocercus*. The generic characters are:—

Tæniidæ, *Tæniinæ:* Rostellum massive, columnar, armed with double row of hooks and resembling an actinia. Suckers prominent, set at base of rostellum and pointing forward and outward. Neck absent; segmentation begins immediately caudad of suckers. Adults in intestine of carnivorous mammals. Larva a "*Strobilocercus*" Sambon, 1924 (i.e., a segmented *cysticercus*, in which the head is introverted within the anterior end whilst the bladder, greatly reduced, is at the caudal end; body more or less segmented; the proglottids occasionally with genital primordia).

Soon after the publication of my paper Professor Henry Ward informed me that he thought I was safe in making the thick-necked tapeworm of the cat a new genus, but that he thought my designation pre-occupied. Later, Professor Stiles wrote that often he had been on the point of recognizing a special genus or subgenus for *Tænia crassicollis*. His tendency, however, was towards the subgenus. He enclosed proof of a paper which he and Miss Orleman were sending to press. In it he says:—

"This newly proposed genus (*Reditænia* Sambon, 1924) is of interest in human medicine, from two points of view, namely, *a* (*b*). As parasites of man:—

"(1) *Tænia infantis* Bacigalupo, 1922 (*Semana méd.*, 302-305, figs. 1-5), has recently been described as a new parasite of man in Argentina. It bears a remarkable resemblance to *T. tæniæformis* of cats, and if it is a valid species it is to be classified in the same genus with the tapeworm of the cat.

"(2) *Tænia crassicollis* Rudolphi, 1810a, is synonymous with *T. tæniæformis*. On account of a folk custom of eating chopped liver of mice in cases of retention of urine, this worm has long been under suspicion as a possible parasite of man (but its occurrence in man is as yet doubtful).

"*b* (*a*). Because of the concurrence of cancer in the liver of rats with the presence of *Cysticercus fasciolaris*.

"Whether, or not, the characters advanced by Sambon will be accepted as of generic value will depend largely upon individual conceptions of taxonymy. Conservatively they might be accepted as of subgeneric rather than of generic value, but admittedly this is a subjective opinion.

"Attention may, however, be invited to the point that if *Tænia tæniæformis* is accepted as representing a genus or a subgenus distinct from *Tænia* (*Tænia*) type *T. solium*, and *Tænia* (*Tæniorhynchus*) type *T. saginata*, the new generic name *Reditænia* falls into synonymy, for it is antedated by two other names, *Megacephalos* and *Hydatigera*, both based upon the same species as genotype.

"*Megacephalos* Goeze, 1782a, 42, was based upon the larval form *Tænia vesicularis fasciolata* (× *Cysticercus fasciolaris*) of the rat. The question arises, however, whether this name is available in nomenclature. The nomenclatorial practices of Goeze, 1782, are so confusing and subject to such subjective interpretation that the senior author of this paper circularized a number of helminthologists about thirty years ago with the proposition that Goeze, 1782, be eliminated from consideration in nomenclature because of the inconsistencies. Several of

stance seemed almost entirely obliterated. But the observations of Regaud, Bridré, Saul, Conseil, McCoy, Woolley, Wherry and others established the association of worm and neoplasm; moreover, the recent and numerous experiments of Bullock and Curtis, who, indirectly, had repeatedly obtained the production of sarcoma in the livers of laboratory rats by feeding them with the eggs of the cat's tapeworm, seemed irrefutable.

Immediately after the lecture which I had the honour of delivering at the Pasteur Institute in Paris, on December 10, 1924, Professor Borrel invited me to go with him to Strasbourg. There he kindly presented me with some of his old sections of cancerous rat-livers showing to perfection the growing of tumours, almost bud-like, out of the fibrous protective tissue which forms the strobilocercus, cyst wall. Figs. 19, 20, 21 and 22 are photographic reproductions of these sections made by Dr. A. Leslie Sheather, M.R.C.V.S. Fig. 19 shows a large spindle-celled sarcoma in a rat's liver and fig. 20 an epithelioma in a rat's kidney, both arising from the encapsulating host-tissues surrounding the early forms of *Hydatigera tæniæformis*. In many other cases the neoplasm has been described as completely enclosing the living bladder-worm and thus resembling a solid gall such as we see on the leaves of the willow enclosing the larva of a Saw-fly (*Nematus*), but not actually produced by it.

Then, again, Professor Fibiger's well-known obser-

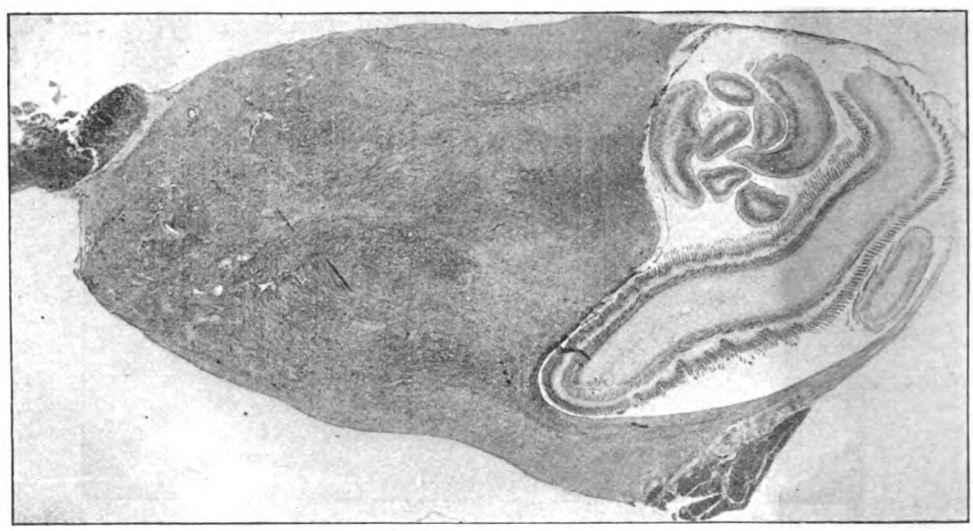

FIG. 19.—Large spindle-celled tumours arising from cyst of *Strobilocercus fasciolaris* in liver of rat.

Goeze's names had however become current and the proposition did not meet with favourable response. Accordingly, he bowed to the view of the majority and accepted Goeze's names. To recognize *Megacephalos*, 1782, at present might produce confusion in other groups, the extent of which cannot be immediately foreseen. The following technical names of the same derivation have been proposed: *Megacephala* Latr., 1802, coleopt.; *Megacephala* Meig., 1824 (supergeneric), dipt.; *Megacephalon* Gray, 1846, aves; *Megacephalus* Fitz., 1843, rept. Partly on basis of the principle that current nomenclature should not be disturbed unless the necessity therefore is clear under the International Code, and partly on the premise that we have grave misgivings as to the availability (under the International Rules) of Goeze's name *Megacephalos*, we are unwilling to assume the responsibility of accepting it.

"*Hydatigera* Lamarck, 1816b, 153-154, was proposed to contain (1) *Cysticercus fasciolaris* of rodents, (2) *C. fistularis* of the horse, and (3) *C. cellulosæ* of man, &c. The first species, *C. fasciolaris*, was later definitely designated as genotype. *Hydatigera* is on a different basis from *Megacephalos* and under Articles 25 and 26 of the International Code this name undoubtedly takes precedence over *Reditænia*.

"The purpose of inviting attention to this point is to prevent if possible the use of the generic name *Reditænia* in medical literature with the certainty in view that it would have to be changed later. If the new taxonomic unit proposed is accepted by authors as of either generic or subgeneric value, the correct name will be *Hydatigera* with *Reditænia* as synonym."

In this Report, as suggested by Professor Stiles and Miss Orleman, whose reasoning I appreciate throughout, I have adopted the name *Hydatigera*, proposed by Lamarck in 1816, but Stiles' view concerning Goeze's names, as he himself states, is not shared by the majority of zoologists. Dr. F. A. Bather, F.R.S., a member of the International Commission on Zoological Nomenclature, whom I have consulted about Stiles' opinion, holds that the names coined by Goeze in 1782 should have currency. He says: "No particular objection being taken to *Megacephalos*, it is therefore admissible. The point is then made that *Megacephalos* may conflict with several other names of the same etymology, but slightly different spelling. If we hold to the purely nomenclatorist attitude that in all and every case the difference of a single letter constitutes a difference of name, then *Megacephalos* must be retained. If we consider that *Megacephalos* should (as I for one hold) have been written *Megacephalus*, then it conflicts with *Megacephalus* Fitzinger. Others might hold (as I do not) that it conflicts with *Megacephala* Latreille. But even so, all these variants are at least twenty years later than *Megacephalos* Goeze. Therefore, on this count also *Megacephalos* must be retained."

Mr. C. Davies Sherborn, Bibliographer to the British Museum (Natural History), also thinks that Goeze's name, *Megacephalos*, was probably intended as a subgeneric name and should be retained as such, or raised to generic rank if opportune.

Dr. H. A. Baylis holds that Goeze's name, if retained, should be retained as originally spelt; others insist on emendation.

Who is right?

"Quot homines, tot sententiæ!"

vations on the gastric carcinoma of rats brought about by the parasitism of the rat-gongylonema (*Gongylonema neoplasticum*) were fully confirmed by experiments similar to those of Bullock and Curtis in the case of the liver sarcoma, viz., by feeding laboratory rats with the large American Cockroach (*Periplaneta americana*), found in the sugar-refineries of Copenhagen, but imported with raw sugar from the West Indies, and harbouring the encysted larval forms of *Gongylonema neoplasticum*.

Other nematode parasites, such as *Trichosomoides crassicauda*, had been incriminated as factors in the production of tumours in rats, while Borrel had long ago described neoplasms of the rat's skin the onset of which appeared to have been incited by a species of *Demodex* peculiar to the rat.

The discovery that at least two rat-tumours—a liver sarcoma and a gastric carcinoma—are usually brought about through the agency of parasitic worms, to wit a cestode and a nematode respectively, was, it seemed to me, a step of considerable oncological importance.

Supported by these facts, the likelihood of the agency of certain helminths and other minor parasites in the production of malignant tumours in animals and man became a subject of the greatest interest and one demanding close investigation. The striking difference noticed in the visceral location of cancer in the inhabitants of different countries found a natural and reasonable explanation in the different and corresponding location of certain helminths peculiar to the inhabitants of such countries, the

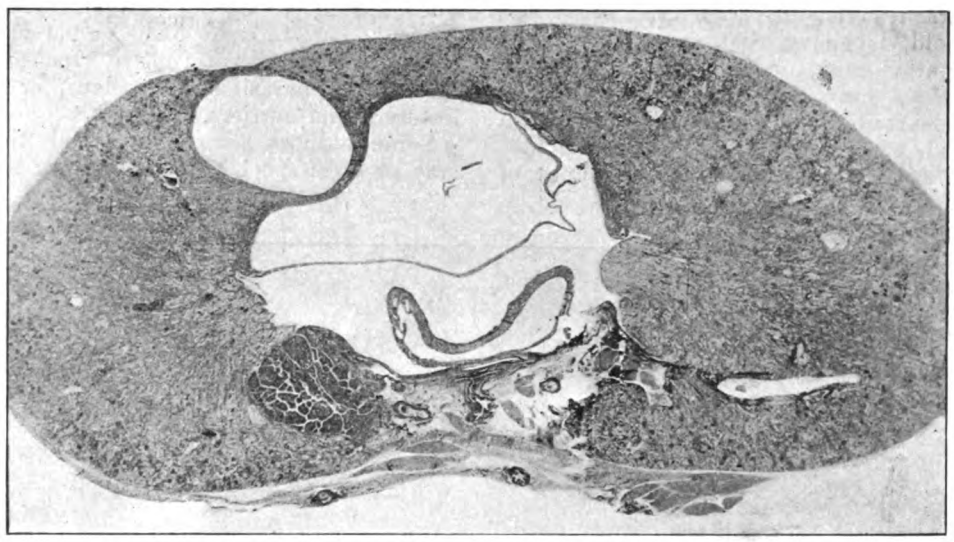

FIG. 20.—Kidney of rat with epithelial tumours arising from multilocular cyst.

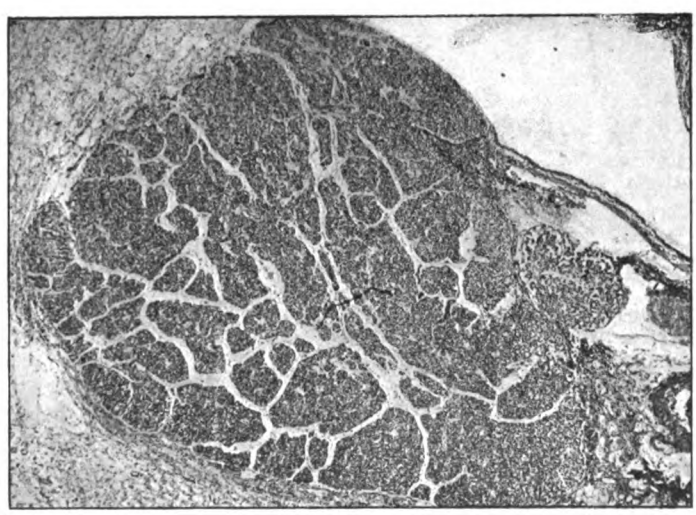

FIG. 21.—Epithelial tumours in rat's kidney.

obvious explanation being supported by actual facts long known. I need but mention the comparatively greater prevalence of cancer of the urinary bladder and rectum in Egypt in the presence of *Schistosoma hæmatobium* and *Schistosoma mansoni* which respectively affect these organs, and the greater prevalence of primary hepatic cancer in China, Malaya and Japan, where *Schistosoma japonicum*, *Clonorchis sinensis*, *Opisthorchis felineus*, and other liver parasites abound.

It is still held, I believe, that repeated or long-continued irritation may, under certain conditions, give rise to the formation of neoplasms. The smoking of a short-stemmed clay pipe is alleged to be a cause of cancer of the lower lip in England, whilst betel-chewing is held responsible for cancer of the cheek in Travancore and Saigon, kangri-burn for cancer of the thigh and abdominal wall in Cashmere.

Against these incriminations are opposed the obsolescence of the clay pipe, the frequent presence of lip-cancer in non-smokers, the rarity of oral cancer in the betel chewers of Tonquin and other countries of the Areca palm, the absence of kangri-cancer in Southern Italy, where the "scaldino," a portable charcoal stove, exactly similar to the Cashmerian kangri, but without any insulating basket-work covering, is very generally used. I readily admit, however, that the irritation associated with peculiar habits may well be a predisposing factor in the production of localized forms of cancer which are restricted to certain peoples and places. The same might be said of "occupational cancer." This being so, surely it is not unreasonable to expect that irritation due to parasitism also should lead to tumour-growth in organs infested by certain helminths and account for the localization of the disease in those particular organs which happen to be the usual habitat of each one of these parasites within its respective geographical area. For, surely, if worms, mites, or other irritant parasites do have any causal relationship to cancer the sooner we know it the better. Then should we be able to control such forms of cancer, as are brought about by parasitism, through the adoption of preventive measures directed against the parasites themselves, or against their fosterers and carriers, if any.

Some authors have conjectured that parasites may produce special growth-inciting secretions, but this is hardly likely, seeing that not one species, but many, belonging to the most sundered groups of parasites, are concerned. Indeed, when several or many individuals of the same species of parasite invade any organ (the liver, for instance, in the case of *Strobilocercus fasciolaris*), they do not all give rise to neoplasms: one or two only do so, if any, rarely more. Besides, in many cases, it is not the parasite itself that produces the neoplasm, but its ova, and these act merely in a passive way like inert foreign bodies which certainly often have been the starting point of cancers. Moreover, the production of cancer is not a constant, inevitable sequel of infestation by the incriminated parasites, but, on the contrary, an infrequent one.

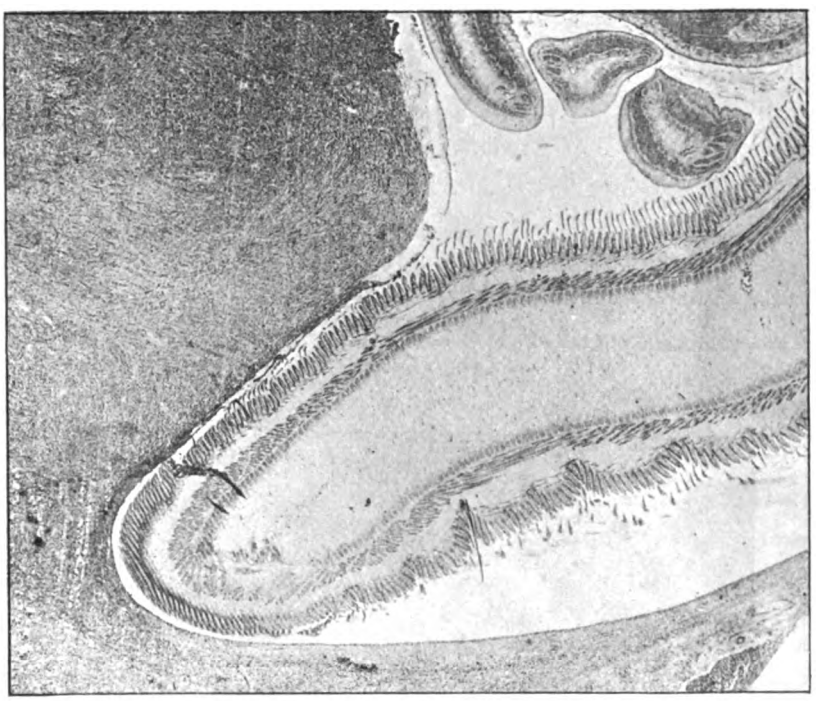

FIG. 22.—Larval form of *Hydatigera tæniæformis* embedded in sarcoma of rat's liver.

GONGYLONEMA.

As stated in previous reports, researches made by Dr. Baylis and myself in Italy during the autumn of 1924, had elicited the fact that *Gongylonema* was present in the cattle, sheep, goats and hogs of the provinces of Bologna, Ravenna and Trento, though with greatly varying prevalence in the different animals examined and in the different districts visited. With regard to man, we knew that *Gongylonema* had been found, not only in several of the States (Arkansas, Florida, Georgia, Louisiana) of the American Union, by Ward, Stiles and Ransom,

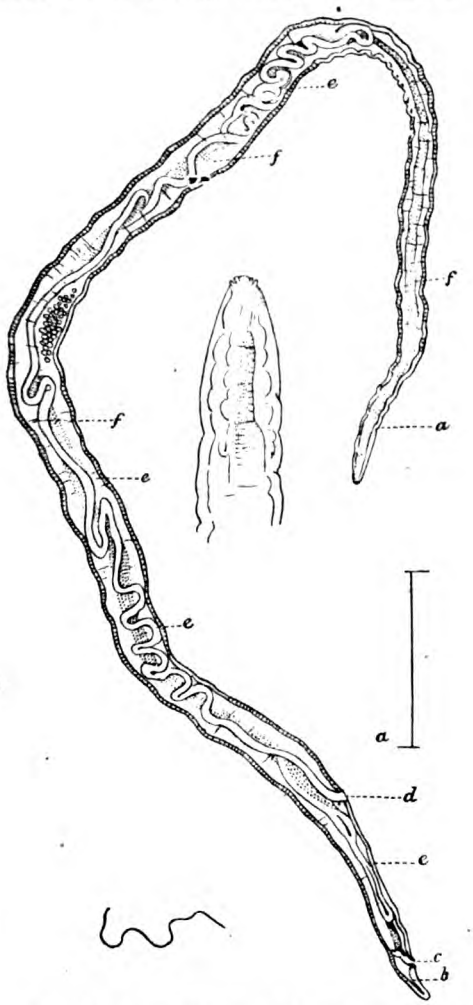

FIG. 23.—Pane's "*Filaria labialis*," a *Gongylonema*, probably *G. pulchrum*. From the original drawing by Paolo Panceri, 1864.

but also in Italy by Alessandrini in a young woman of Saracinesco, near Rome, in 1914, and by Professor C. Pane, of the University of Naples, in a medical student, in 1864. Pane described his specimen under the name of *Filaria labialis*, but a drawing by Panceri enabled me to make the diagnosis of *Gongylonema sp.*, a diagnosis readily accepted by Stiles, Ward and Baylis.

During my visit to Holland I looked for *Gongylonema* and had the good fortune of seeing it at the Amsterdam Municipal Slaughter House. Dr. Bonne had informed Dr. Reeser, Superintendent of the Abattoir, that I desired to look for the presence of *Gongylonema* in Dutch breeds of cattle, sheep and hogs, and when, on April 24, I called by appointment on Dr. Reeser at the superb Amsterdam Abattoir, he told me that Dr. Veenstra had purposely opened up a large number of bovine gullets in the morning and found the required parasite in one of them. This was the first time that *Gongylonema* was looked for and found in the land of the beautiful black and white oxen which are believed to be the direct descendants of the ancient Aurochs. Together with Drs. Reeser, Bonne and Veenstra, I examined many other gullets of cattle, sheep and hogs, but with negative result. Some days later, at the Harlingen and Leeuwarden slaughter-houses, with the aid of the local veterinarians, Dr. Bonne and I examined more than sixty sheep, but the result was again negative. Since May last, Dr. Ferwerda has examined 2,100 more sheep at Harlingen with negative result.

The *Gongylonema* specimens found at the Amsterdam Abattoir were typical of *Gongylonema scutatum* and numbered about twenty in the one œsophagus, including both males and females.

At the Dutch Cancer Institute, I had the pleasure of meeting Dr. W. F. Wassink, who showed me several parasitic nematodes which he had been studying with a view of ascertaining what part they played, if any, in the causation of tumours. Among these worms were *Gongylonema neoplasticum*, *Heterakis isolonche*, *Trichosomoides crassicauda*, *Hepaticola sp.* Dr. Wassink had already published two very interesting papers, one on *Heterakis* and the growths to which it gives rise, the other on *Gongylonema neoplasticum*, detailing his researches and experiments which confirmed and extended Fibiger's work. Dr. Wassink very generously allowed me to take away some of his material in order that I might study it more closely from the parasitological point of view. I was particularly pleased to secure a mouse *Gongylonema*, the only one remaining, I believe, out of several found in six mice caught in a sugar refinery of Amsterdam which was said to be entirely free from rats.

The first *Gongylonema* ever described—the type species of the genus—is *Gongylonema minimum* Molin 1857. It was found by Rudolphi in the house mouse (*Mus musculus*) "circa ventriculum et in hepate" and mentioned in his Synopsis (1819) under the name of *Filaria musculi*, but without either description or figure.

Under the heading "? Filaire de la Souris" Dujardin (1845) states that a mature female specimen of Rudolphi's parasite, sent from Vienna to the Paris Museum, in 1816, measured 21·6 mm. in length by 0·154 mm. in thickness. It presented two lateral membranous alæ in the anterior portion and a tapering but blunt-ended posterior extremity. The elliptical ova measured 45 microns long by half that size in thickness. These characters, he thought, suggested a *Spiroptera*. Only two mice had been found infested out of 1,274 examined.

It was the Italian helminthologist, Dr. Raffaele Molin, who first proposed, in 1857, the genus *Gongylonema* for this parasite, which he described under the name of *Gongylonema minimum*. His description, he tells us, was based on several specimens, male and female, some free, others embedded in a piece of liver, from which they were extricated with difficulty.

Molin's description reads as follows:—

"*Gongylonema minimum*.—Os orbiculare, inerme, Corpus capillare, inerme, flexuosum, breve; extremitas anterior maris attenuata, apice nudo, obtuso, bulbillis parvis, coarctatis; extremitas anterior feminæ attenuata, apice obtuso, bulbillis, magnis, discretis; extremitas caudalis maris inflexa, sensim attenuata, subtus excavata, fovea elliptica, magna, utrique limbis amplis, singulus quatuordecim papillis elevatis, decem ante, quatuor infra aperturam genitalem, vagina penis dipetala; extremitas caudalis feminæ subito attenuata, inflexa; apertura ani prope apicem caudalem; apertura genitalis feminæ in posteriore corporis parte, ab apertura ani remota—Longit mar. 4‴ (8·8 mm.); Longit. fem. 8‴ (17·5 mm.)."

Molin adds that examining the sheath of the penis, at first sight it appears to be a ligulate sheath, but lightly compressing the caudal extremity of the male between two slides the said organ spreads apart into two branches like a forceps and, being released, at once returns to its former shape. The female's long oviduct was full of embryonated eggs.

Speaking of Dujardin's brief description of this nematode, Maurice C. Hall (1916) says: "Dujardin notes a specimen from Vienna as having two cervical alæ. This would suggest that he was not dealing with *Gongylonema*." But in this case there seems to have been some mistake, for the presence of cervical alæ more or less developed and often festooned, is characteristic of *Gongylonema*. On the other hand, the presence of gongylonemas in the liver ("embedded in it") as noted in the Vienna Museum catalogue and also reported by Molin—who says he had considerable difficulty in extricating them—suggests confusion, I think, between *Gongylonema* and a liver-inhabiting Trichinellid since separated from other Trichurinæ by Hall (1916) and given the new generic name of *Hepaticola*.

In Wassink's mouse specimen some of the ova were extruded through a break in the body-wall and oviduct. Thus I had the opportunity of examining them out of the body and singly. They were in different stages of development, some containing fully-formed, coiled-up embryos, others as yet unsegmented. The shells of the fully-matured eggs were elliptical, presenting at each pole a distinct opercular line, but in the earlier stages the polar capsules seemed absent and the embryonic mass enclosed in a membrane protruding at each end of thick egg-shells in the shape of headless barrels.

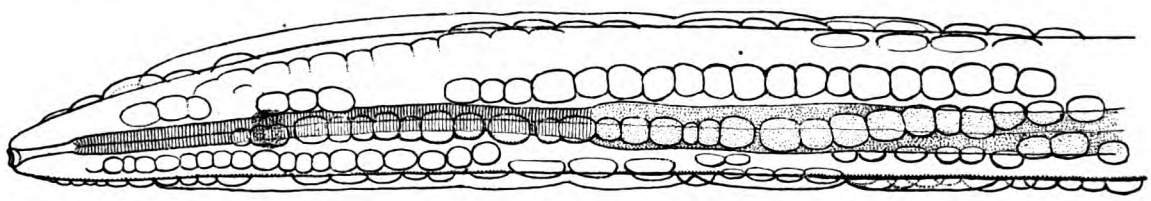

FIG. 24.—Anterior end of *Gongylonema* from mouse.

GONGYLONEMA IN MAN.

In the JOURNAL OF TROPICAL MEDICINE AND HYGIENE (February 2, 1925), in a note following the publication of my Paris lecture on the Epidemiology of Cancer, I stated that Professor Giulio Alessandrini had briefly reported, in 1914, a case of gongylonema infestation in "I. O.," a young woman of Saracinesco, near Rome. Six worms were present, occupying sinuous galleries at the base of the tongue. Alessandrini proposed the name of *Gongylonema subtile* for this parasite, which he considered to be near *Gongylonema pulchrum*, but differing from it in being longer, more slender, and having the studded anterior portion more extended and the eggs smaller and more elongate.

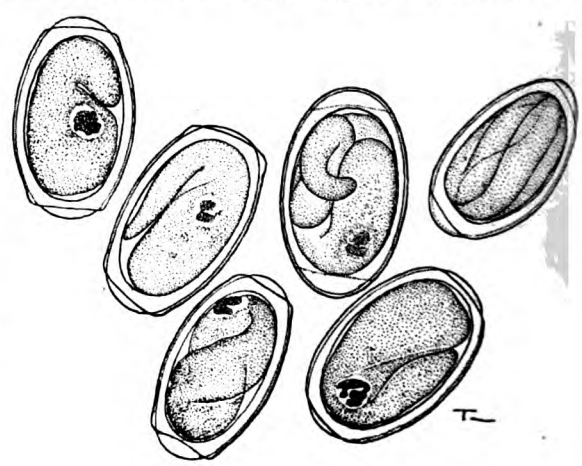

FIG. 25.—Eggs of mouse *Gongylonema*.

Last June, Professor Alessandrini came to London to attend the International Sleeping Sickness Conference and kindly brought us two of the gongylonemas he had been able to obtain from the Sara-

cinesco case. These worms seemed to differ in no appreciable way from specimens of *Gongylonema pulchrum*. Dr. Baylis carefully examined and measured Alessandrini's specimens and came to the conclusion that on morphological grounds they could not be distinguished from those found in cattle, sheep and hogs. These, he considers, belong to one and the same species, a species which, so extended, by right of priority, should be called *Gongylonema pulchrum*.

Personally, on account of slight differences in size (smaller size) and visceral location (more frequent presence in oral cavity and tongue), reported by various authors, I was inclined to consider *Gongylonema pulchrum* apart from *Gongylonema scutatum*, but, after comparatively examining several specimens myself, I do not feel justified in considering it more than a host-race, if that.

The question of specificness often is very difficult to settle. Already in 1892, Professor A. Railliet had pointed out the great similarity between *Gongylonema scutatum* and *Gongylonema pulchrum*, but had cautiously reserved judgment until male specimens should be forthcoming. These were eventually found by Fayet at Tabessa, in Algeria, and sent to Professor Neumann, who, however, retained the two species, remarking that they were "tout à fait voisines," differing only slightly in size.

Slight differences in body size, relative distance between certain parts of the body, acumination of posterior extremity, length of spicules, seem far too slender, far too variable to permit of specific distinction, yet if constant in the same kind of host, they would indicate the establishment of "host races." There can be no doubt that in parasites which have a wide zoological distribution, and especially in those whose life-cycle is spent in two alternating hosts—a vertebrate and an invertebrate brought into close association by peculiar biological conditions—the host environment may be more or less favourable and may determine certain adaptive modifications of size and shape in the parasite, or a change in its visceral location, just as variable surrounding conditions may cause colour and other variations, or a change of station, in free-living species of wide geographical distribution.

In a paper on "The Hæmogregarines of Snakes," published in the *Transactions of the Pathological Society of London*, in 1907, I suggested for parasites the recognition of "host-varieties" or "host-races" corresponding to the so-called "geographical races" of free-living animals. When adaptation, to a new environment in the case of free-living animals, or to a new host in the case of parasites, becomes marked and constant, then the differentiation acquires specific value, but the recognition of "race" has many advantages; it avoids a bewildering multiplicity of names and manifests the zoological distribution of the parasite, a matter of no little importance to the sanitarian in preventive work.

Often I had found considerable difficulty in writing up differential descriptions of certain hæmogregarines, leucocytozoa and other blood protozoa obtained from closely allied host-species, yet in certain cases I was fully convinced of their specificness. My studies had taught me that hæmogregarines differ specifically in different host-species when the latter belong to different zoogeographical regions, and this specificness is supported by the far more easily determinable specific differences present in the several metazoan parasites concomitantly infesting these same host species. On the other hand, certain species of hæmogregarines, like certain species of metazoan parasites, may be found in a variety of hosts belonging not only to closely-related species, but also to different genera, or even families, provided the latter inhabit the same zoological region and are attacked promiscuously by the same species of blood-sucking ectoparasites.

When I went to Italy last summer, I determined to go to Rome, visit Professor Alessandrini and, through him, get in touch with "I. O.," the Saracinesco case, in order to endeavour to find out where and how she had become infested. Unfortunately, when I reached Rome, on July 28, I was told that Professor Alessandrini had left the day before for his summer holidays. However, I found Dr. Alessandro Carega, the physician who had examined Signorina I. O., extracted two of her worms, and given the latter to the Roman parasitologist for determination. Then, through the report of a fatal accident to a man of the same family, who had been crushed by a motor car, whilst employed at the Costanzi Theatre, I was able to trace, after many peregrinations, the *Gongylonema* patient herself.

Whilst in London, Professor Alessandrini had given me a history of the case which I published in the JOURNAL OF TROPICAL MEDICINE AND HYGIENE, September 1, 1925. Here is the more complete account which Dr. Carega gave me from his case book:—

"In 1912, a young woman of Saracinesco—Irene Ottaviani—came to my surgery to consult me about a small worm which she said she had drawn out of the mucous membrane of her mouth and brought for me to see, rolled up in a scrap of paper. The said worm, dried up and shrivelled, could not possibly be recognized, and I thought I had before me one of those strange cases of hysterical simulation (as of women who pretended they had vomited beetles, toads, lizards or snakes) so frequently described by the gullible physicians of the seventeenth and eighteenth centuries. But the patient insisted on the truth of her statement and told me that some months previously, whilst residing at Tivoli, she had extracted a similar worm by scraping with her nails a tiny prurient nodule which from time to time formed on the floor of her mouth, beneath the tongue. Yet, finding no alteration whatever in her oral mucosa, I asked her to return at the first reappearance of the nodules she had described. After a few days she returned, stating that a new nodule had formed, and at once I proceeded to make a careful examination.

"*Clinical Examination.*—Irene Ottaviani is seventeen years of age, unmarried. Her father died of some acute illness the nature of which she does not remember, her mother succumbed quite recently to uterine carcinoma which had recurred after operation. The patient herself has been always well. She was born at Saracinesco, on May 14, 1895, and lived there until five years old, then at Sambuci up to the age of thirteen or fourteen. During the last few years she has lived alternately at Saracinesco and Sambuci and, within the last eight months, at Tivoli. She is a healthy young woman of robust constitution; all her organs and systems appear to be in sound condition.

"The examination of her mouth reveals a small, whitish nodule the size and shape of an acne pustule, on the floor of the mouth, on the left side and a little below the frenulum linguæ. Close to this nodule one sees a small, red streak which, examined through a magnifying glass, looks like a small, purplish-red serpentine about 3 cm. long.

"Holding the mucosa stretched by means of a pair of forceps, I incised the white nodule with a lanceolate needle and extracted a small worm which at once coiled itself, snake-like, about the needle. This worm is of whitish colour, about 2 cm. long, cylindrical, rather tough, slender as a horse-hair and actively motile.

"Thinking it might be some rare helminth, I took it to Professor Alessandrini for determination. He said it was probably a new species of *Gongylonema* near *Gongylonema pulchrum* and begged me to let him publish the case. To this I consented willingly, since the chief interest of the case was its parasitological curiosity."

Informing Dr. Carega that I intended to visit the various places where his patient had resided, in order to find out, if possible, where and how she had contracted her gongylonema infestation, I said that I had but one day—the following—which I could devote to this object. I proposed that he, Signorina Ottaviani and her married sister should go with Dr. Pan and myself to Tivoli, Sambuci and Saracinesco. Though very busy that day and the next, Dr. Carega kindly put off all else and decided to go with me, "because," he said, "detective work in medicine is a somewhat novel idea."

So, at six o'clock in the morning of September 1, we packed ourselves in a Fiat car and left Rome by the Porta Maggiore. At this gate, originally an archway of the Claudian aqueduct, no less than ten conduited waters meet and, of these, three came from the region we were about to visit. We crossed the desolate, fever-reeking Campagna studded with the triumphal arches of ancient aqueducts and with the ruins of villas and tombs of a mighty race. Few monuments are so impressive as those Roman brick-work structures carrying rivers on their backs for hundreds of miles. But, even more important and wonderful is that vast, unseen network of endless subterranean canals and reservoirs which already in pre-Roman times drained Saturn's land and made it healthy.

I was still musing over the unrivalled sanitation of the ancients, when we passed the ruins of Hadrian's villa and began to ascend the hill on which Tivoli proudly holds out its graceful Sibylline temple over the roaring falls of the Anio. The road winds through an olive wood, a strange assemblage of gnarled, split trunks bearing crowns of grey-green foliage, then leads into "Tibur superbum," the resort of Emperors, noblemen and poets, sung by Horace and Catullus; now a squalid little town. Here Irene Ottaviani resided for about one year, in a large building of the Via del Trevio. Here, after eight months, she had noticed the presence of strange thread-worms beneath her tongue.

From Tivoli we drove to Sambuci, passing through land far more fertile than that of the Campagna. The Sabine and Tiburtine hills rose before us bare and wild and we reached the Fiumicino, or Rio Sambuci. Here, close to an old convent, which for six years had been the patient's home, we found mules awaiting us with pads to ride upon and halters instead of bridles.

After a pause to instruct people to collect house- and stable-vermin against our return, we bestrode our sure-footed mounts and began the climb. The narrow mule-path crept along the brink of deep ravines and, of course, our mules chose the very edge of the precipice. So, we ascended, clinging to the mountain sides, until we reached the little village with its old Saracenic fort looking like a part of the stony mass on which it is built.

We were entertained at the quaint "albergo," kept by Irene's eldest sister, and enjoyed a glorious view from the inn's balcony. Before us stood the Tiburtine and Cornicolanian mountains, between them roared the Anio, beyond lay the open Campagna with the river rushing through it the sooner to reach Rome, faintly looming in the distance. The old Roman wolf-legend took new meaning: there, at our feet, was the lupine Anio suckling the Eternal City made of its substance—grey-white travertine—hard, compact, imperishable, as anyone can see in Roman structures of all periods, such as the Colosseum and Bernini's colonnade in the Vatican Square.

After luncheon we climbed the narrow stair-like streets of Saracinesco cut out of the mountain limestone, reached Irene's earliest home and the Saracenic fastness, avoiding, on the way, the unwieldy black hogs who infest the village. Then we left, with a cloud of white doves rising and fluttering before our advance. These coral-footed messengers belonged to a castle fronting the heaped-up village and built by one of its daughters who, many years ago, went to Rome, sold flowers, was courted, became travelled and wealthy, yet never forgot her wild mountain home, nor her sandalled, sunburnt sisters, with their laughing faces and bright, intrepid eyes.

On our way back from Saracinesco, at Sambuci, we were met by boys with bottles and boxes full of cockroaches, cellar-beetles, scorpions and other creeping things. With them came

Irene's cousin—Dr. Francesco Scornajenghi—the local health officer, who told us he had practised for over twenty-four years in the district of Sambuci, which comprises the mountain village of Saracinesco. Cancer was common at Sambuci and Saracinesco, but he remembered years without a single case, others with several. In Sambuci the disease affects chiefly the breast and the stomach, in Saracinesco, strangely, the stomach and the lip, but never the breast. During his long practice, he had not seen a single case of mammary cancer in Saracinesco, but epithelioma of the lower lip was common, both in men and women, though the men smoked little and the women never. Black beetles (*Blatta orientalis*), as we were able to notice ourselves, swarmed in almost every house. He told us that Irene's mother had died of cancer of the womb.

We visited the convent where Irene had lived. Originally, it had been a Franciscan monastery, but when the monks were turned out, it became a tenement-house for men, mules, oxen, swine and rats. Now, thoroughly white-washed, it is the retreat of black-robed nuns who school the little children of Sambuci.

At the back of the convent was a large orchard with peach, cherry, fig and walnut trees; beyond, a boulder-strewn hillock crowned with oaks. Here

FIG. 26.—Signorina Ottaviani, Dr. Carega and the writer at Rio Sambuci. (Photo by Dr. Pan.)

Irene used to play, but her toys were mud and pigs. Over a hundred hogs had been penned close to the convent and we saw the "porcareccia," or piggery, where they had wallowed in mud and filth. "Yet, my only amusement," said Irene, "was feeding the swine with acorns, or teasing them: there was nothing else to do."

On the hill grazed a flock of sheep and some silver-grey cows with wide-spreading horns. Lower down, by the Fiumicino, were many oxen, goats and swine. Irene told me that she had drunk of the water of the stream by the bridge where it meanders shallowly among the boulders and is polluted by the droppings of the wading and drinking herds.

At about five in the afternoon, we left Sambuci and whizzed through the wide Campagna inhaling the air of the meadows scented by the fragrance of the good herb mint.

I asked the patient what she experienced whilst the worms lodged in her mouth. "I felt," she said, "a gentle pulling, a slight tickling or formication (formicolio) caused by something like hairs, or very fine threads, which I could not see, but felt distinctly within the lining of my mouth. I endeavoured to grasp these living threads, but, invariably, they slipped from between my fingers. I managed to hold them, at times, by means of a handkerchief, but though I battled long I could not draw them out. At length I succeeded, and the first two worms I threw away, well pleased to be rid of them."

In the evening, Dr. Carega, Dr. Pan and I met on the Pincio, at the Casina Valadier, to discuss our day's work. Rome—Eternal Rome—lay at our feet stretched out like a prayer carpet, whilst the great, soaring dome of St. Peter stood silhouetted against the flaming sky.

Signorina Ottaviani had told us that the first worm was noticed by her at Tivoli on August 1 of 1912, after a residence of about eight months; the second at Saracinesco on October 2, 1912; the third, again at Tivoli, on November 3 of the same year; the fourth also at Tivoli a few days later and the fifth and sixth in Rome, on April 5 and July 14 of the following year. Considering time only, infection might have taken place in Tivoli, but this was unlikely, because in Tivoli she had inhabited a large, clean, well-built house in the very middle of the town, and her life there had been one of indoor work exclusively. At Sambuci and Saracinesco, on the contrary, she had lived a rural life, nearly always in the open and in constant touch with all kind of animals, such as mules, oxen, sheep, goats and especially hogs. Both in Sambuci and Saracinesco one cannot take a step in any direction without meeting swine; they wallow at the very doors of houses, go in and out of rooms. The streets belong to them; they seem to be the masters and so have been since, and long before, the days of Varo. In Saracinesco, whilst Dr. Carega complacently scratched the ear of one of these portly creatures, a white sow, which seemed eager to make our acquaintance, I asked the innkeeper how they could tolerate such gross, unclean, unshapely beasts about them. "A few minutes ago," retorted he, "you told me our hams were the best you had ever tasted!"

The worms extracted from Irene's mouth and brought to London by Professor Alessandrini could not be distinguished from *Gongylonema pulchrum* of swine and, during our trip up the valley of the Aniene, swine had been much in evidence, both at Sambuci and Saracinesco, but especially at Sambuci. So, no doubt, Professor Henry Ward was right when, determining the first *Gongylonema* found in man in America, he told us that, probably, it was *Gongylonema pulchrum*, though the specimen sent him for determination was a single immature female.

A similar diagnosis was made by Alessandrini,

who had the good fortune of obtaining three mature female worms, but was induced by the importance of the discovery of *Gongylonema* in man to create a new species.

From these and other considerations, such as the size of the worms and their presence within the oral cavity and about the tongue, a location not infrequent in swine, I hold that the gongylonema found in man in Europe and America is *Gongylonema pulchrum* Molin 1857, and that the names *G. labialis* (Pane 1864), *G. subtile* Alessandrini 1914, and *G. hominis* Stiles 1921, are but synonyms of *G. pulchrum*. Further, like Baylis, I am inclined to add to these synonyms also *G. ransomi* Chapin 1922, especially as true swine (*Suidæ*) are confined to the old world, and domestic pigs were not introduced into America before the seventeenth century. The "Razorback," now found almost exclusively in the South, is the oldest new-world porker, a degenerate descendant of the pigs that were brought to America by the earliest white settlers.

Gongylonema in Villa Lagarina.

On reaching Villa Lagarina, we at once started looking for *Gongylonema* in all those animals—mammals and insects—which we knew might harbour it in one or other of its developmental stages. We looked for the adult forms in rats, mice, sheep, goats, hogs and oxen, and for the larval forms in cockroaches, cellar-beetles, meal-worm beetles, and dung-beetles.

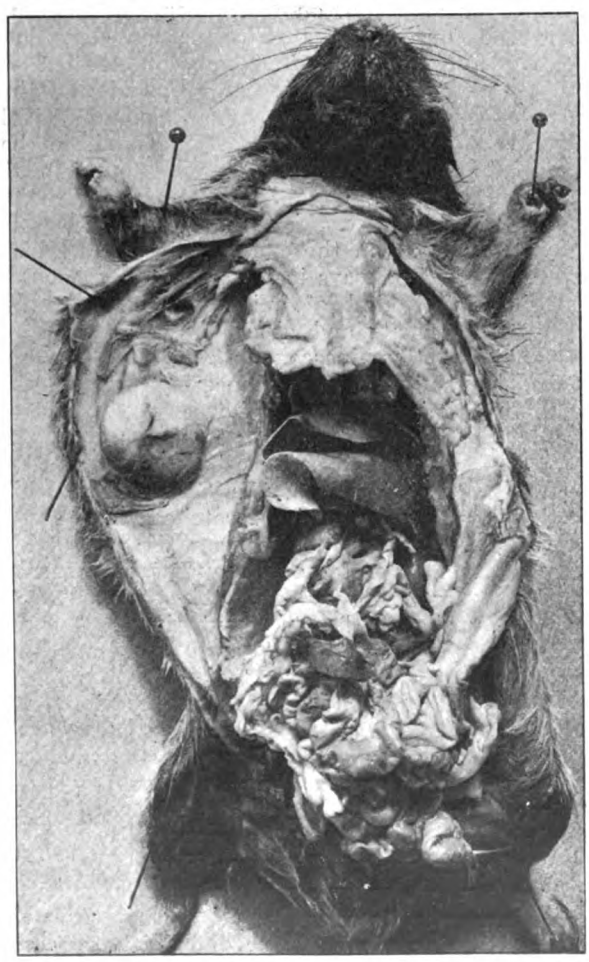

Fig. 27.—Villa Lagarina rat with fibro-adenoma of mammary gland and malignant papillomatous growth in stomach.

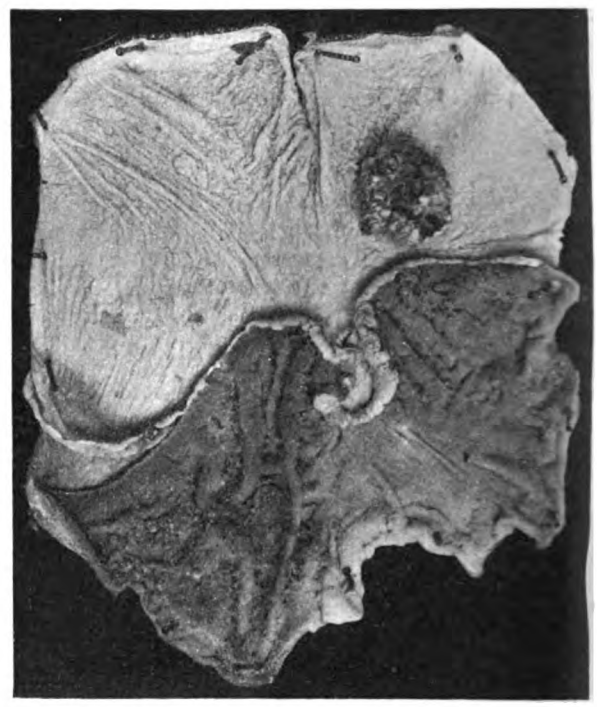

Fig. 28.—Carcinoma in cardiac portion of rat's stomach with *Hepaticola gastrica* embedded in growth.

With the aid of Dr. Scrinzi and the local chemist, we made known that we offered to pay a reward for each rat and mouse captured alive or freshly killed. We organized a rat-catching squad of boys, bought and distributed numerous traps of various types and made arrangements with the chemist who kindly undertook to pay for us the premium, receive the dead rodents, slit them open and place them in a formaldehyde solution to await dissection and examination. Thus we thought we had started a formidable crusade against the Lagarina rats and mice, but the first week's output was so disappointing that we decided to increase the reward to ten times the original figure. Yet the higher premium brought no better results. The people told us it was a bad season for rat-catching. Most of the rats and mice were out in the fields, where they could find plenty of food, and those who remained behind were exceedingly wary and shunned traps.

Then I placed a number of steel-traps myself in the most likely places and with every precaution, following the instructions so clearly set forth in the book on "Rats and How to Destroy Them," recently published by our late, much regretted, associate, Mr. Mark Hovell. I was greatly helped in this work by a young, intelligent local butcher, Signor Claudio Agostini, who took the keenest interest in our inves-

tigations. Consequently, a dozen rats were soon caught; all belonged to the same species, *Rattus norvegicus*, and one of them, an aged female, trapped in the neighbourhood of a pigsty, proved of the greatest interest, being affected by two different neoplasms: a mammary tumour on the right side, above the third nipple and a large papillomatous growth in the cardiac portion of the stomach. The latter neoplasm seemed to have grown out of worm-galleries excavated in the gastric pavimentous epithelium by a Trichurine worm of the genus *Hepaticola*. Dr. Bonne undertook the study of these neoplasms and his sections show that the mammary growth was a benign fibro-adenoma, whilst the gastric tumour was a true cancer, an epithelioma, with a worm or worms involved in its fabric. Sir Lenthal

FIG. 29.—Œsophagus of heifer from Villa Lagarina with numerous *gongylonemas* beneath epithelium.

Wheatle, who has examined Dr. Bonne's slides, fully agrees with his findings and statements.

We captured and examined about ninety rats in Villa Lagarina, twice finding mammary tumours, but once only carcinoma. In no case did we find any *Gongylonema*, though a majority of the rats were infested with other nematodes such as *Trichosomoides* in the urinary bladder and *Hepaticola* in the cardiac portion of the stomach. On the other hand, all the local cattle, slaughtered at Villa Lagarina, presented more or less numerous gongylonemas bedded in the œsophageal epithelium. The first gongylonema seen in a Lagarina bovine was found by the butcher's sister, a girl of sixteen, to whom I had shown a photograph of a sheep's gullet full of these worms sheltered in their sinuous galleries. After this her brother Claudio scrupulously examined every œsophagus and constantly furnished us with material for our experiments.

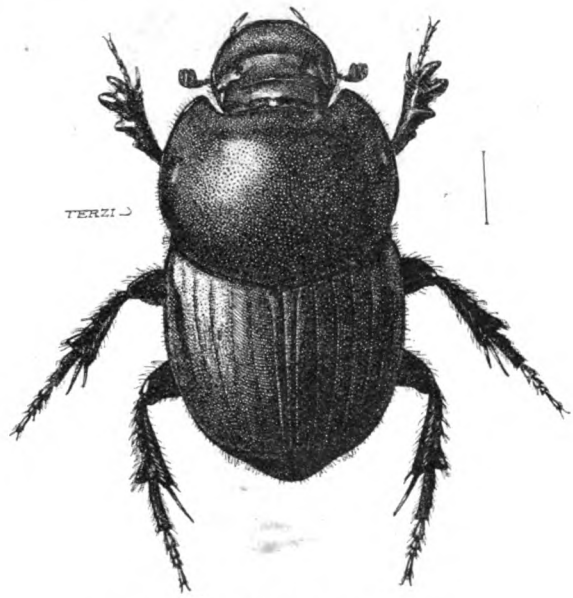

FIG. 30.—*Onthophagus taurus*. ♀.

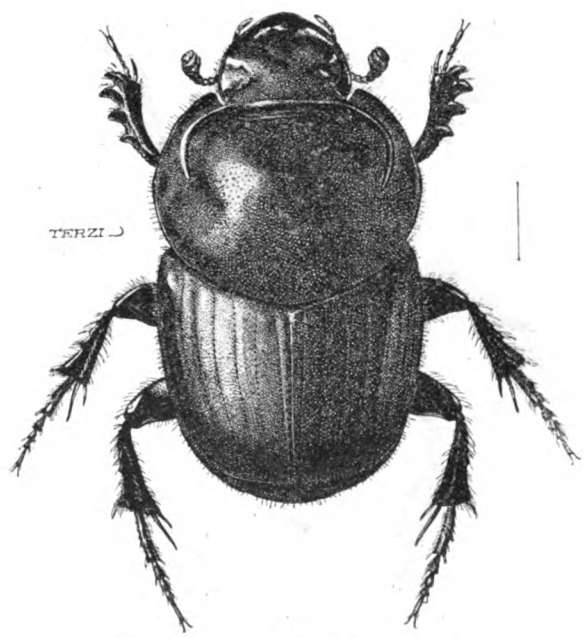

FIG. 31.—*Onthophagus taurus*. ♂.

Notwithstanding the absence of gongylonemas in the mice and rats we were able to capture in Villa Lagarina, we carefully examined cockroaches (*Blatta orientalis* and *Blattella germanica*), cellar-beetles (*Blaps lethifera*), and meal-worm beetles (*Tenebrio*

molitor and *T. obscurus*), but invariably with negative results.

On the other hand, the examination of dung-chafers proved that these lamellicorn beetles did harbour the larval stages of the species of gongylonema found in the local cattle. Several kinds of dung-beetles were collected in Villa Lagarina and its immediate neighbourhood and determined by Mr. Blair; they were the following: *Onthophagus taurus*, *O. opacicollis*, *O. furcatus*, *O. muchicornis*, *O. lemur*, *O. ovatus*; *Aphodius subterraneus*, *A. fimetarius*, *A. hæmorrhoidalis*, *A. erraticus*; *Caccobius schreberi*, *Gymnopleurus strumi*, *Oniticellus fulvus*, *Copris lunaris*, and *Geotrupes mutator*. Of these, only four were found to be harbouring the encysted larval forms of *Gongylonema*, they were: *Onthophagus taurus*, *Oniticellus fulvus*, *Caccobius schreberi*, and *Aphodius hæmorrhoidalis*, all of which are new to science as hosts of *Gongylonema*. Indeed, hitherto, no one seems to have studied the intermediary hosts of the cattle gongylonema (*Gongylonema scutatum*) in Europe.

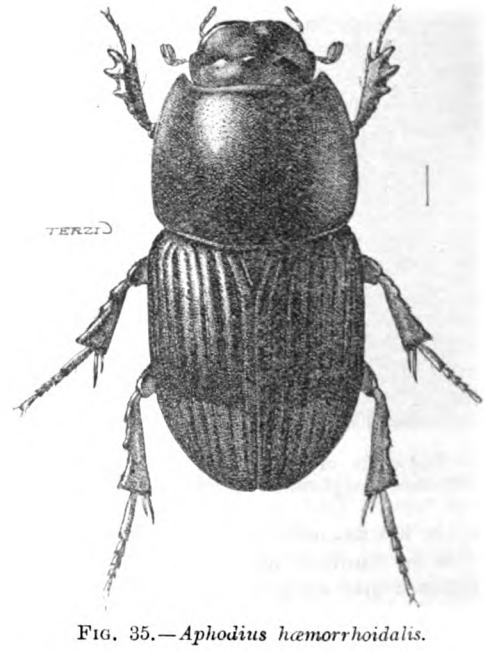

FIG. 35.—*Aphodius hæmorrhoidalis*.

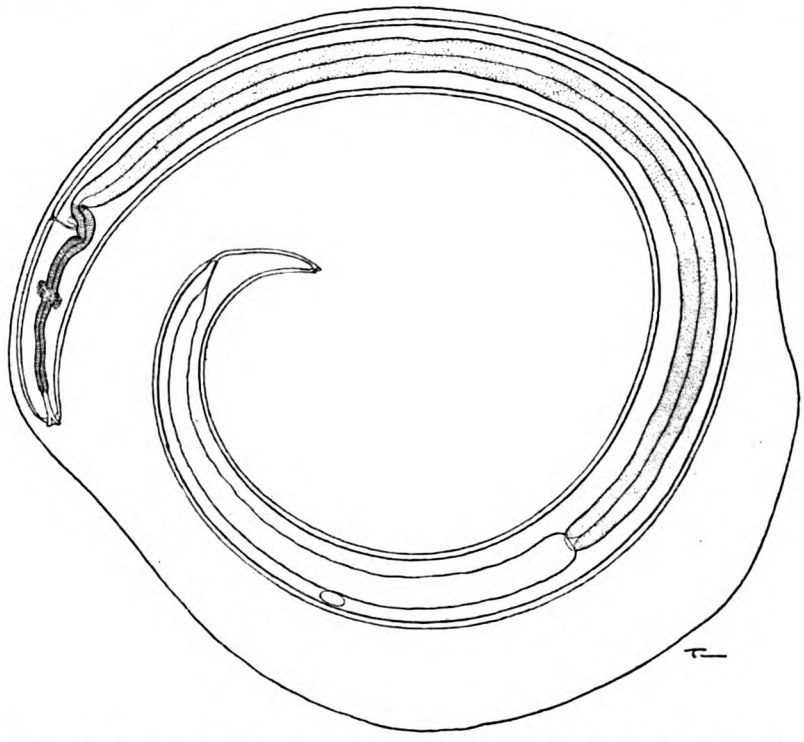

FIG. 36.—Encapsuled *Gongylonema* larva (third stage) from *Onthophagus taurus*. (× about 110.)

The dung-chafers were collected by Drs. Baylis and Pan, Mr. Blair and myself in the droppings of cattle in various places where cows used to be taken out to graze. One of the more convenient places was behind the church, an area of waste land through which ran, or rather trickled, a small brook. Another good place was the strip of communal land

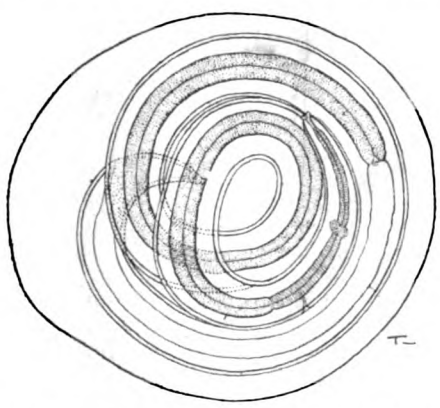

FIG. 37.—Encapsuled *Gongylonema* larva (third stage) from *Onthophagus taurus*. (× about 100.)

along the left bank of the river Adige. Pats of cow-dung, in the open, usually swarmed with dung-beetles, of one or more kinds, and with the larvæ of various kinds of flies. In stables, dung-chafers were never found. Therefore, it is obvious that the infestation of oxen must take place in the open and that the cattle must necessarily swallow, possibly

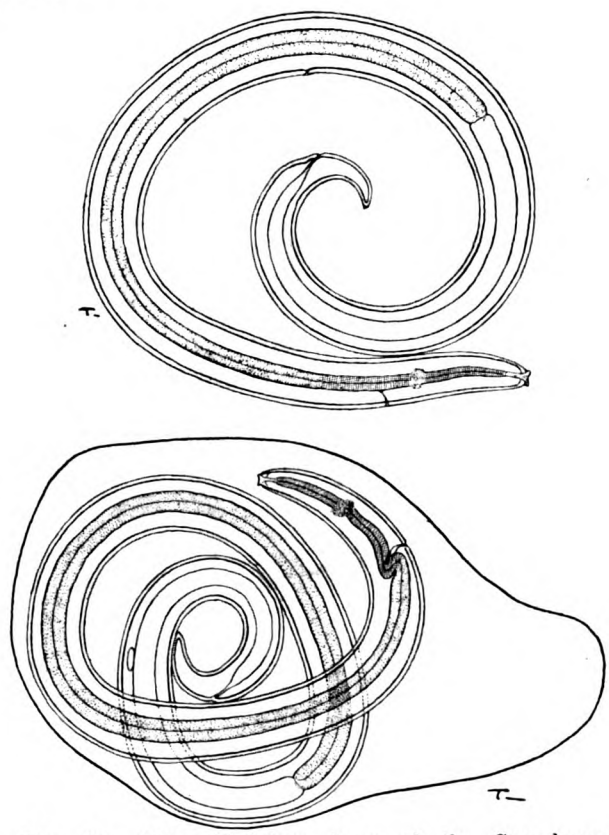

FIG. 38. — Two third-stage larvæ of the *Gongylonema* of cattle, from an experimentally-infected *Blattella*. (× about 100.) One larva is still enclosed in its capsule, the other has been liberated.

with the grass, gongylonema-infested dung-chafers who, in turn, become infested in excrement containing the eggs of the worm. It is possible, however, that larvæ of the third stage may be taken up by cattle, or man, in water, having escaped from crushed insects trodden under hoof or drowned in shallow water. Indeed, fully developed larvæ may leave their cysts and live in water for days. It was probably by drinking at the Fiumicino fords that Signorina Ottaviani contracted her infection. One day, frightened by a savage sheep-dog, she drank deeply of the muddy water.

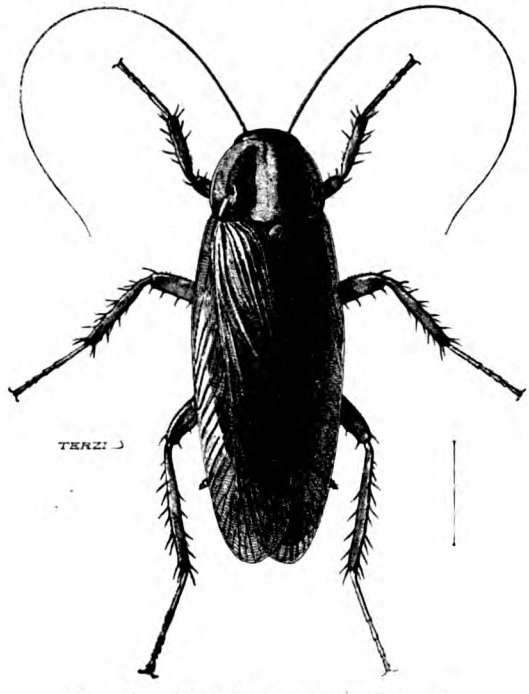

FIG. 39.—*Blattella germanica* (L.). ♀.

Several experiments were made to ascertain whether household insects could foster the larval forms of *Gongylonema scutatum* and whether the larvæ of the cattle form, artificially reared in these insects, or naturally fostered in their usual alternative hosts—the dung-chafers—could continue their development and reach full maturity in rats. These experiments proved successful and of great interest. In the first place, the two available kinds of cockroaches: *Blatta orientalis* and *Blattella germanica* were fed on gongylonema ova taken from worms found in the gullets of sheep and oxen, with the surprising result that while the German cockroach (*Blattella germanica*) was easily infected, the larger and darker Oriental cockroach (*Blatta orientalis*) invariably proved refractory.

Then several rats were fed on dung-beetles collected at random, of which probably only four or five per cent. were harbouring gongylonema larvæ. Others were fed on the smaller cockroach (*Blattella germanica*) artificially infected and probably always

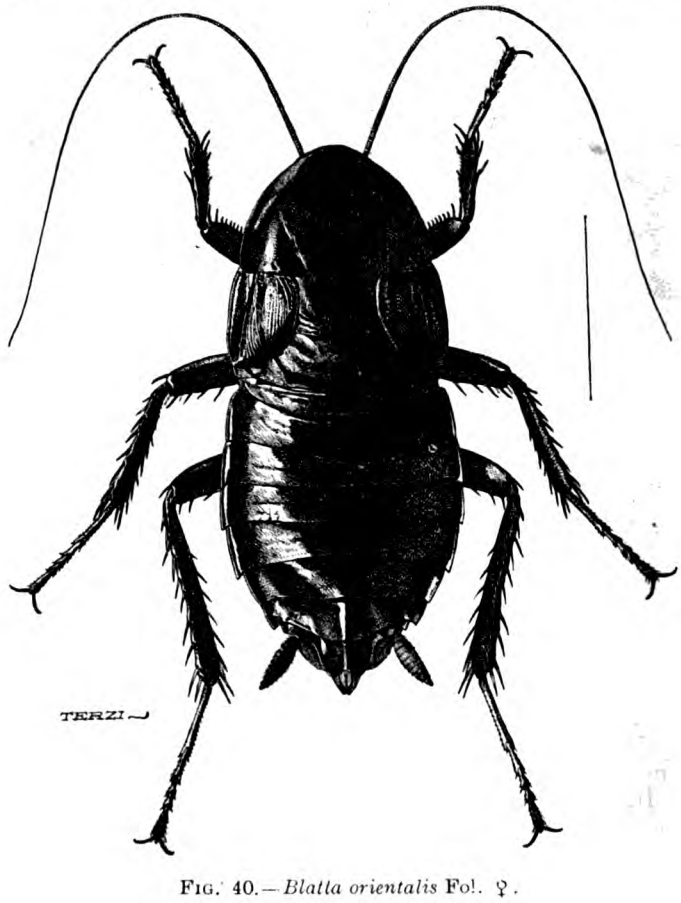

FIG. 40.—*Blatta orientalis* Fol. ♀.

containing many encysted larvæ at the ultimate stage of development. Two of our London laboratory rats, fed on gongylonema larvæ taken from dissected dung-beetles (*Onthophagus taurus, Caccobius schreberi*) and cockroaches (*Blattella germanica*) proved to be infected, and in both cases the recovered worms—a single immature gongylonema in each case—were found, not in the cardiac portion of the host's stomach, as is usually the case with rats naturally or artificially infested with the rat gongylonema (*Gongylonema neoplasticum*), but in the œsophagus, which is just as constantly the natural habitat of cattle and sheep gongylonemas within their definitive hosts. However, too much importance must not be given to this location, because the rat gongylonema may also affect the œsophagus and tongue in naturally infected rats and frequently the œsophagus in laboratory infected rabbits and guinea-pigs. These experiments have been fully detailed in a paper by Dr. Baylis, who, assisted by Dr. Pan and my daughter, Miss Juliet Sambon, carried them out in Trento under the most trying conditions, in an improvised laboratory—at times a veritable furnace.

If the gongylonema found in cattle be the same as that infesting swine, then, as suggested by Dr. Baylis, *Gongylonema pulchrum* Molin 1857 is the correct name for it and *Gongylonema scutatum* (Mueller 1869) necessarily falls into synonymy. Likewise, if rat and mouse do harbour the same species of gongylonema, as I am inclined to believe, then the rat and mouse gongylonema should retain the name *Gongylonema minimum* given it by Molin in 1857, when he first described it and made it the type species of his new genus of Spiruroid worms. This being so, the names *Gongylonema musculi* (Rudolphi 1819), Neumann 1894 and *Gongylonema neoplasticum* (Fibiger and Ditlevsen 1914), Ransom and Hall 1916, would fall into synonymy. Rudolphi's name *Filaria musculi* was a nomen nudum and Dujardin's "Filaire de la Souris" a vernacular name, therefore neither has any status whatever in nomenclature. The latinized name proposed by Neumann in 1894 is antedated by Molin's name *Gongylonema minimum* 1857. However, there are difficulties. With regard to the gongylonema of swine, as I have already stated, there are slight differences in size and visceral location which distinguish it to a certain extent from that of cattle, and, with regard to the mouse gongylonema, we should not forget the smaller forms found by Rudolphi in Austrian mice and described independently by Dujardin and by Molin. The recognition of host-races, or subspecies, would overcome these difficulties.

Examination of the gullets of cattle infested with gongylonema often revealed papillomatous growths

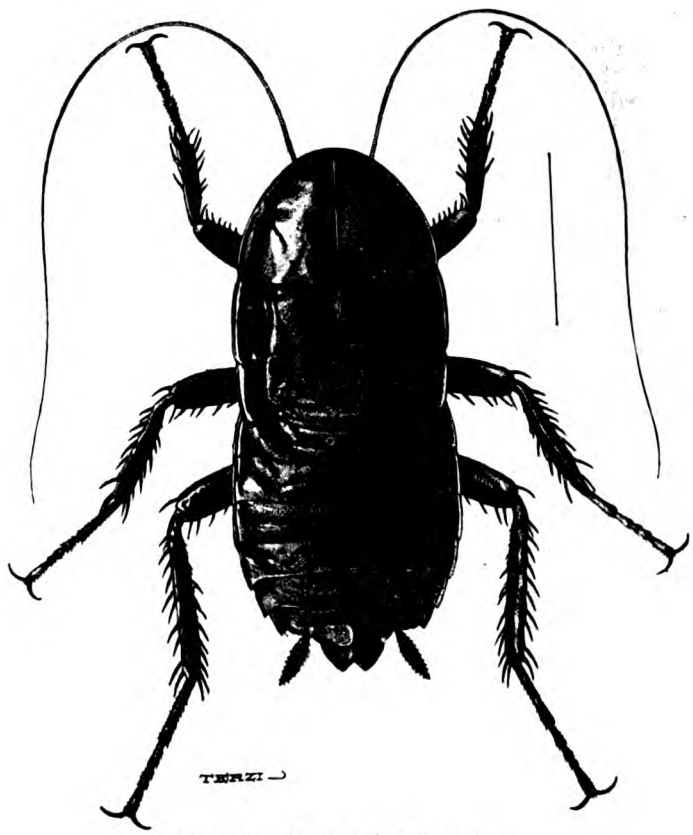

FIG. 41.—*Blatta orientalis* nymph.

in the form of nodular, villous or coralline prominences, but I have no reason to suppose that they were necessarily dependent on the presence of the worm. I have seen identical proliferations of the papillæ and their overlying epithelium in gullets of cattle without gongylonema, and in animals bred in districts apparently free from this parasite.

We did not go to Villa Lagarina solely to study *Gongylonema;* our object was to endeavour to find out, if possible, why cancer showed peculiar limitations in its topographical distribution, why it affected certain houses or groups of houses leaving others, in the vicinity, untouched.

Suspicion having fallen, since long ago, on rats, mice, black-beetles, churchyard-beetles and other vermin infesting old buildings, it was our purpose thoroughly to investigate these house-pests and anything else that might explain well-ascertained restrictions of the disease to particular streets, blocks of houses, or isolated cottages.

As stated, we found no *Gongylonema* in the rats, mice, cockroaches, cellar-beetles and meal-worm beetles of Villa Lagarina, but the number of mice and rats examined was, unfortunately, very meagre. On the other hand, we found *Gongylonema* rampant in the local cattle and dung-beetles. Swine we were unable to examine, because none were being slaughtered at the time, but, from our own researches in neighbouring localities, we know that they do harbour this nematode-parasite when pastured.

The absence or great rarity of *Gongylonema* in household vermin, its restriction to cattle and dung-chafers, whilst necessarily minimising the importance of any part it might play in the incidence of cancer in Villa Lagarina, did not exclude it. Indeed, if Dr. Baylis is right in assuming identity between swine and cattle gongylonemas, the local cattle harboured that very form (*Gongylonema pulchrum*) which has been reported from man both in Europe and America.

Twenty-three cancer cases had been reported in Villa Lagarina since 1884. In none had the neoplasm affected the œsophagus, but three were oral (two palate, one mouth), sixteen gastric and two mammary. In the remaining two the site was not mentioned. Hitherto, *Gongylonema* in man has been found solely about the oral cavity (lips, floor of mouth, tongue).

That *Gongylonema* is capable of favouring cancer growth is fully proved by the numerous observations and experiments of Fibiger, Wassink, Yokogawa and others on the gastric carcinoma of rats brought about both naturally and experimentally by *Gongylonema neoplasticum*. Moreover, whilst carrying out our parasitological researches in Villa Lagarina we had the good fortune of finding a wild rat with a gastric carcinoma associated, not with a *Gongylonema*, but with another nematode, a new species of *Hepaticola*, which, like *Gongylonema*, excavates sinuous galleries and oviposits between the layers of the pavement epithelium of the cardiac portion of the host's stomach. Had *Gongylonema* been there instead of *Hepaticola*, no doubt the same result would have followed. Indeed, when Baylis and I first found *Hepaticola* living in galleries burrowed within the epithelium lining the cardiac portion of rats' stomachs, we both thought and, in our papers of 1924, suggested that probably *Hepaticola* might bring about the formation of neoplasms just like *Gongylonema*. This prevision has now been verified.

An Italian veterinary surgeon, Major S. Raffaelli, has just made an inquiry into the prevalence of *Gongylonema* in food animals slaughtered at the abattoirs of Ravenna, Cesena, Forli, Faenza, Imola and Bologna. He examined 1,970 bovines and found *Gongylonema* in 20 per cent. In sheep, of which he examined 2,800, he found the percentage as high as 70. He examined 330 swine and found *Gongylonema* only once in a hog that had been reared in the open. In fifteen equines he found nothing, whilst in 490 birds (fowls and turkeys) he says he once found *Gongylonema* (? *Gongylonema ingluvicola*) together with "molti *tricocefali* o meglio *tricoblasti*" (? *Capillaria*). These results agree in every way with those previously obtained by Baylis and myself in Bologna and Faenza, in the autumn of 1924.

In the Trentino we found the distribution of *Gongylonema* infestation in cattle to vary considerably in different places. In a general way, we found it to be very prevalent in the Lower Valley of the Adige, infrequent or, maybe, totally absent in the region of the Upper Adige and in the valleys of La Pusteria.

A New Species of Hepaticola.

In October, 1924, Dr. Baylis and I examined a number of rats caught in the yard of the Municipal Slaughter House at Bologna and found their livers literally crammed with the ova of *Hepaticola hepatica*. The egg-masses embedded in the hepatic substance gave the more or less cirrhotic livers the peculiar speckled appearance characteristic of coccidiosis. In the stomachs of these same rats we found nematode-worms lying within sinuous galleries excavated in the stratified squamous epithelium of the cardiac portion. At first sight we thought we had found specimens of the rat gongylonema (*Gongylonema neoplasticum*), but examination of the extricated worms proved that they were not gongylonemas, but Trichurinæ of the genus *Hepaticola*. We noted the unusual location of these worms and, at the time, thought that previous authors had overlooked this location and described them solely from the liver. Here, certainly, they (*Hepaticola hepatica*) are usually found, often dead and disintegrated, within tracts filled with their resistant lemon-shaped ova. The material collected in Bologna (livers and stomachs of infested rats) was brought to London and deposited in the Zoological Department of the British Museum (Natural History).

Last summer, in Villa Lagarina, again we found *Hepaticola* in the stomachs of several of the rats examined, but here the livers of the infested ani-

mals were all normal and entirely free from *Hepaticola* eggs. This fact was striking and instructive. Remembering my observations on the two schistosomes (*Schistosoma hæmatobium* and *S. mansoni*), which, frequently together, affect man in Egypt, I felt certain that in the case of *Hepaticola* also we were confronted by a similar duality of species, each one affecting its own particular habitat.

Obviously, the whip-worm, *Trichocephalus hepaticus*, first described by T. L. Bancroft, of Brisbane, New South Wales, in 1893, and given generic rank, under the name of *Hepaticola*, by Hall in 1916, was not present in the Villa Lagarina rats examined by us, but was found in the Bologna rats together with another, hitherto undescribed, gastric species again

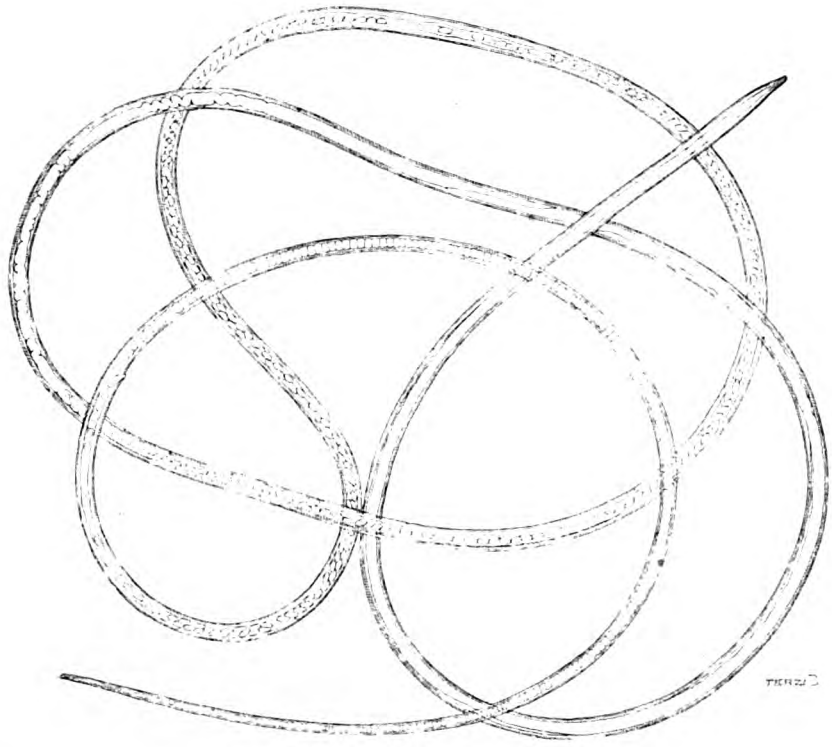

FIG. 42.—*Hepaticola gastrica* (original).

found, but this time alone, in the rats of Villa Lagarina. I believe I shocked my colleagues when I informed them, somewhat dogmatically, that we had before us a new species of *Hepaticola*, differing biologically, and no doubt morphologically also, in body and eggs, but my excuse is that I was fully convinced of the fact and needed no closer scrutiny or exact measurements to affirm it. Indeed when, on his return to London, Dr. Baylis was able to compare the *Hepaticola* eggs laid within the worm-galleries in the gastric epithelium of the Villa Lagarina rats with those taken from the livers of the Bologna rats in his keeping, he recognized the correctness of the assertion. His recent paper on the subject (JOURNAL OF TROPICAL MEDICINE, August 1) gives a description of the new species and details the differences found between the ova of *Hepaticola hepatica*, with their radially striated outer shell, and those of the new species which, owing to its visceral location, has suggested the correlate name of *Hepaticola gastrica*.

Hepaticola gastrica is the parasite we found in the Villa Lagarina rat presenting a gastric carcinoma. In this case, the worms were found not only in galleries between the layers of pavement epithelium which line the cardiac portion of the rat's stomach —some of them at the very base of the papillomatous tumour—but, as Dr. Bonne's sections clearly show, in the very growth itself, suggesting that they, their eggs and galleries, had been incorporated in the neoplasm the growth of which they may have incited. Maybe, the worms had actually sown those specific organisms which had produced, first the papillomatous growth, then, later, its conversion into a veritable cancer by a process of metabiosis, such as is witnessed in the ripening of certain soft cheeses in which successive micro-organisms follow and displace one another, one species being necessarily dependent upon the action of another.

The latter view is confirmed by the researches of Wassink in Holland, who showed me evidence of *Hepaticola* associated with tumour formation in the stomach of Amsterdam rats, and of Beatti, in Buenos Aires, who, on three occasions, found tumours (papilloma, sarcoma and epithelioma) in three different rats harbouring a gastric hepaticola

which, tentatively, he mentioned under the name of *Hepaticola hepatica*, but which no doubt must have been our *Hepaticola gastrica*.

These observations made by us in Italy, by Wassink in Holland, and by Beatti in the Argentine, show that, under suitable conditions, *Hepaticola gastrica*, like *Gongylonema neoplasticum*, may favour, or even incite, the production of neoplasms in the rat and, maybe, in man also, since species of both *Gongylonema* and *Hepaticola* have been found to occur in *Homo sapiens*.

Hepaticola hepatica, as I have stated in discussing the mouse *Gongylonema*, was first seen by Rudolphi (1819) and Molin (1857), but both confounded it with *Gongylonema minimum* Molin 1857, discovered in the same mouse. This is obvious from the fact that while some of the worms (*Gongylonema*) were lodged in the stomach, others (*Hepaticola*) were " in hepate " (Rudolphi) and " were extricated with difficulty from the piece of liver in which they were embedded " (Molin). Now we know that no gongylonema has ever been found in the liver, whilst *Hepaticola hepatica* is essentially a liver parasite and that it is most difficult to separate it from the liver substance.

Hepaticola hepatica has been found not only in rats (*Rattus rattus* and *Rattus norvegicus*), mice (*Mus musculus*) and man, but also in the rabbit by Lebert in France, in the common hare by Nicoll in England, and in the prairie dog and beaver by Weidman in America.

Trichosomoides crassicauda.

A worm frequently found in the Villa Lagarina rats was *Trichosomoides crassicauda*. This singular nematode, inhabiting the uropoietic organs (renal pelvis, ureters, urinary bladder), was discovered in Ireland by Bellingham in 1840. Rayer, in 1843, found it in the urinary bladders of brown rats captured in Paris knackers' yards, and proposed to call it *Trichosoma muris decumanis*. Dujardin (1845) pointed out that it differed from Trichosomes especially in the relative length of the anterior and posterior portions of the body and should be placed in a separate genus. Von Linstow, in 1874, made it the type of a new genus for which he proposed the name of *Trichodes*, but this name being preoccupied by *Trichodes* Herbst, 1792, coleopteron, it was changed to *Trichosomoides* by Railliet in 1895.

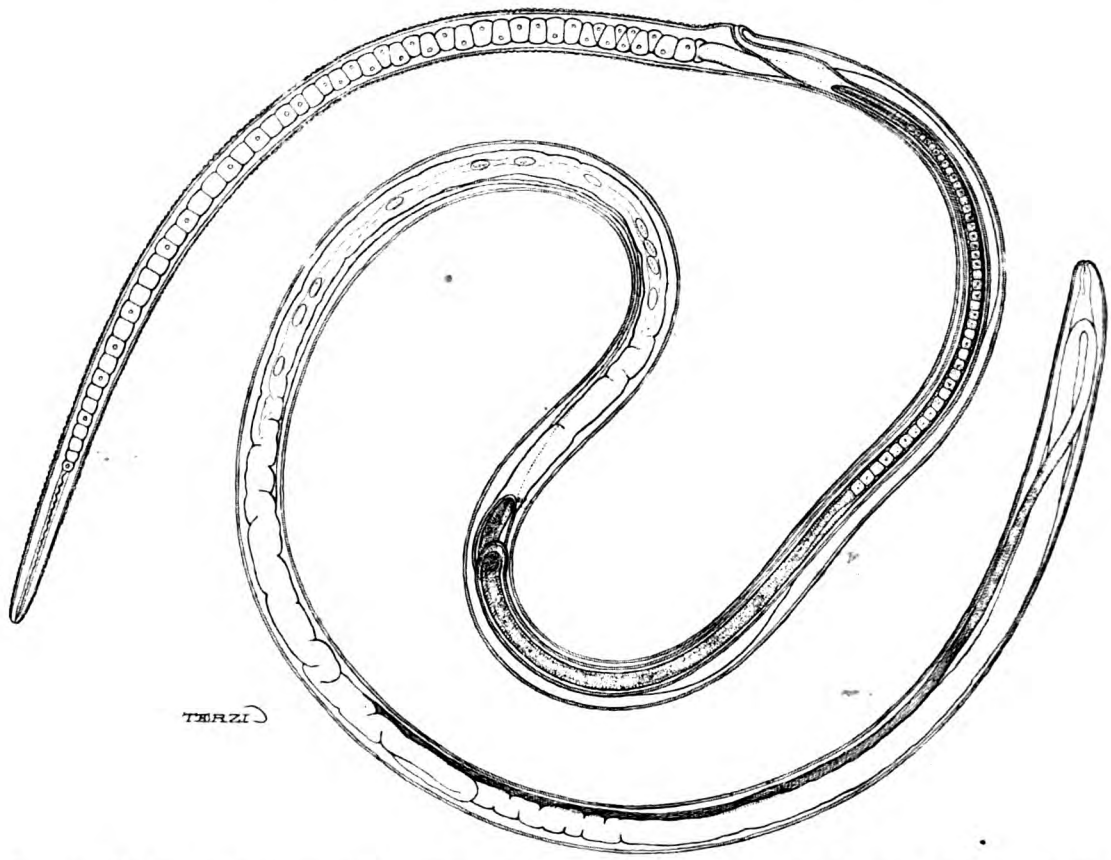

Fig. 43.—*Trichosomoides crassicauda* from urinary bladder of Villa Lagarina rat, male in female's uterus (original).

The mature female occupies the urinary bladder of its host and is a long attenuated worm measuring from 11 to 12 mm. in length. The male, seldom over 2 mm. long, is usually found parasite-like, or rather as an inquiline, in the female's vagina or uterus—a strange case of sexual dimorphism similar

to that of *Bonellia* among the *Gephyrea*, the microscopic males of which live in the female's nephridium, which acts as a duct for the spermatozoa. In young specimens, taken from the pelvis of the kidney or the ureters, the female is only about three times as long as the male it harbours, but, after reaching the urinary bladder, owing to the considerable growth of her reproductive organs, she becomes more than ten times the length of the male now lost in the mass of eggs which fill the uterus. One, two or more males may be found in the same female with their anterior extremities invariably turned towards the sexual aperture. Fig. 43 shows a young female from the urinary bladder of a Villa Lagarina rat with the male *in situ*. The male is easily discernible within the female's body by the bead-like vesicular cells which, as in the female, strung on to the posterior part of the œsophageal tube, are characteristic of all *Trichinelloidea*.

In a paper entitled " Trichodes crassicauda specifica, eine causa directa in der Aetiologie der Tumoren " (*Beiträge zur klinischen Chirurgie*, P. v. Bruns, Band LXXVI, Heft 3, Tubingen), Dr. S. Löwenstein states that he found papillomata and even malignant growths associated with the parasitism of this worm. These changes had occurred not only in the epithelial lining of the bladder where the adult worms usually are found, but, sometimes, also in the ureters and in the renal pelvis. Not only the young worms, but more particularly the eggs seemed to be the cause of epithelial proliferation, and the author thought that the ensuing neoplasms might be the result of some peculiar toxic substance excreted by the nematode.

In Holland, Dr Wassink showed me several rat bladders affected by this parasite. He considered *Trichosomoides* responsible for tumour formation as well as for calculosis, which he frequently found associated with its parasitism.

Papillomas in association with *Trichosomoides crassicauda* have been reported by Saul in 1914 and by Thomas in 1924; both authors found female worms either partially or entirely embedded in the epithelial proliferations.

In Villa Lagarina we found *Trichosomoides* to be rather common; as a rule two or three worms were present in the urinary bladder, but once I counted as many as seven. Twice we found calculosis associated with it, never any new growth.

The scarcity of urinary calculi and the absence of neoplasms in the bladders of the several rats examined in Villa Lagarina, during our short stay there last summer, in no way disproves the agency of *Trichosomoides* in the production of new growths, an agency which has been proved by the observations of Löwenstein, Wassink, Saul and Thomas. Indeed, a parallel example was presented by the larval form of *Hydatigera crassicollis*, which, though frequently found in the Villa Lagarina rats, was never seen associated with sarcoma. Yet numerous observations and experiments have proved, beyond doubt, the agency of this bladder-worm in the production of hepatic sarcoma in rats.

Muspicea borreli.

In a short note appended to the publication of my Paris lecture in the JOURNAL OF TROPICAL MEDICINE AND HYGIENE (February 2, 1925), I described a minute round-worm found by Professor A. Borrel in Strasbourg mice and given me for determination. This worm being unlike any known nematode, I proposed to establish for it the new genus *Muspicea* and call it *Muspicea borreli*. Borrel had found it in the reticular layer of the skin and in the inguinal and mediastinal lymphatic glands, also in and about cancerous tumours of the mammary glands.

Since publishing my note, I have read Haaland's paper on " Spontaneous Tumours in Mice " (*Fourth Report of the Imperial Cancer Research Fund*, 1911). Haaland examined a number of old London mice and found specimens of Borrel's nematode in the connective stroma of the mammary gland, in lung and pleura.

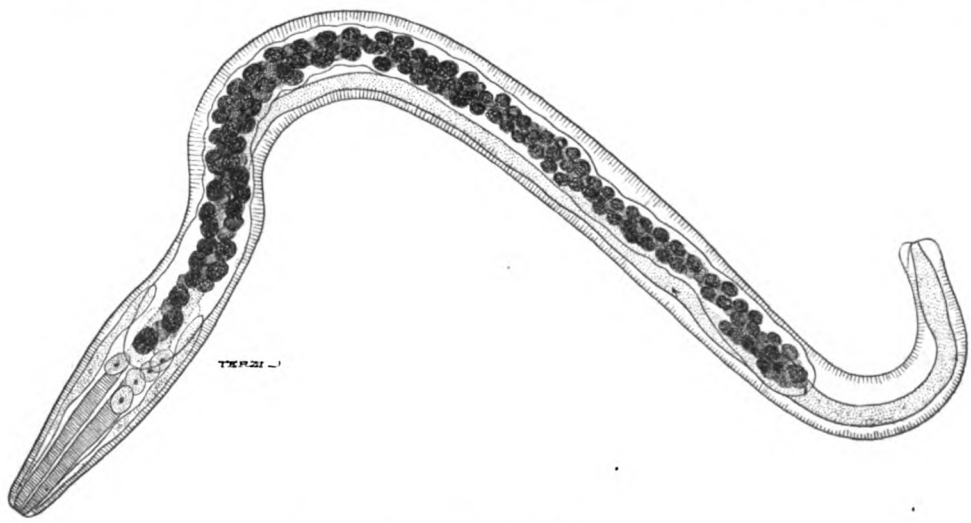

FIG. 44.—*Muspicea borreli* Sambon, 1925.
Young female.

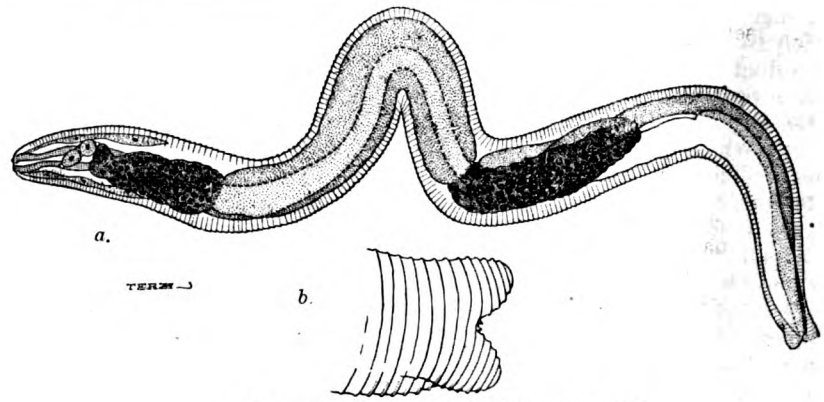

FIG. 45.—*Muspicea borreli* Sambon, 1925
a. immature form. *b*. posterior extremity.

They were exactly like those he had seen previously in Borrel's laboratory, and the photographs illustrating his paper show that they were identical with those I have had the opportunity of examining. The worms found were invariably females, either immature or fully mature, and newly extruded larvæ. The absence of males led Haaland to surmise that fertilization must occur elsewhere.

Specimens of the subcutaneous nematode, together with an intestinal Oxyurid found in the same mice, were sent by Haaland to Professors Shipley and Leiper for identification. These helminthologists identified the Oxyurid as *Oxyuris tetraptera* (since made type of a new genus: *Aspiculuris* Schulz, 1924), and stated that: "The worm in the subcutaneous tissues cannot with certainty be identified with any of the forms described; in general character and mode of occurrence it resembles most closely *Ollulanus tricuspis*."

The male being as yet unknown, it is difficult to assign the systematic position of Borrel's nematode. It is very doubtfully related to *Ollulanus*, as suggested by Leiper and Shipley. The œsophagus only slightly swollen posteriorly, the single uterus, the granular eggs, the viviparity agree, but it differs from *Ollulanus tricuspis* not only specifically, but also generically and very strikingly. Its mode of occurrence is also different.

The female of *Muspicea borreli* measures from 3 to 3·40 mm. in length, that of *Ollulanus tricuspis* barely 1 mm., yet the embryos of the latter measure, according to Leuckart, 320 microns in length, whilst those of the larger nematode measure only 270 microns. The anterior end of *Muspicea borreli* is invariably straight, that of *Ollulanus tricuspis* according to Cameron "usually coiled upon itself" (spirit specimens?). The posterior extremity in *Muspicea borreli* terminates in a bilobed tail with mammilloid lobes between which opens the anus. In *Ollulanus tricuspis* the posterior extremity is produced 0·03 to 0·04 mm. beyond the ventrally placed anal aperture and terminates in three or more cusps. At maturity, *Muspicea borreli* is merely a sack packed with a multitude of embryos all equally developed, while *Ollulanus tricuspis* shows only one to three large embryos at a time (Leuckart).

The embryos described by Leuckart as those of *Ollulanus tricuspis* are not only longer, but almost uniform in thickness throughout and their tail is prolonged into a sinuous appendix. The œsophagus is equal to a third or a half of the total length of the body (Leuckart). Those of *Muspicea borreli* are shorter, broader at the posterior extremity which ends in a bilobed tail preceded by two large papilla-like projections, one on each side of the body; the œsophagus is less than a sixth of the total body length.

Of *Ollulanus tricuspis* only the larvæ are said to be found in mice, usually coiled up and encysted just like *Trichinella* larvæ in the musculature or connective tissue. The adults are parasites of the cat and dwell within the gastric mucosa. Cat and mouse, therefore, are, according to Leuckart, the two alternating hosts in the life-cycle of *Ollulanus tricuspis*.[1] In the case of *Muspicea borreli* the adults (so far only females seen in all stages of development) and new-born larvæ are found free and motile in the subcutaneous tissue and lymphatic glands of mice; the mouse, therefore, is the definitive host and the fosterer of the larval stage; the intermediate host probably will turn out to be some arthropod.

From the first, when he found this nematode, Borrel suspected that it might play some mediate part in the production of cancer in mice. He had found it in association with mammary carcinoma and in a case of lymphoma, also in the subcutaneous tissue of tar-painted mice in process of developing cancer. Indeed he suggested that the presence of the worm and its embryos might explain why cancer develops in some tarred mice and not in others.

Haaland, supporting this view, says: "Whatever may be the life-history of these nematodes, it is natural to associate their presence with some of the local or diffuse inflammatory changes in the connective tissue of the mamma, for which, as yet, there is no other adequate explanation. It is evident that the

[1] Cameron has recently claimed to have shown that what Leuckart regarded as the larvæ of *Ollulanus* in mice were in reality those of *Synthetocaulus abstrusus*, a lungworm of the cat. No other worm belonging to the family Metastrongylidæ of which *Synthetocaulus* is a member, is known to pass through an intermediate host, and Cameron's experiments appear require confirmation.

nematodes are capable of setting up intense inflammatory processes. The site where they have rested for some time (encapsulated?) is lined by a zone of leucocytes, and other signs of inflammation follow their path. This occurs while they are living; when they lie dead in the tissues a violent reaction with leucocytes and round cells and phagocytosis is set up, and the nematodes soon become unrecognizable. The mixture of acute and chronic inflammation in the interstitial tissue with sclerotic changes is quite characteristic and in the majority of cases where this picture has been found it has been possible to demonstrate the round worm. It must be pointed out that the change is essentially one of the loose connective tissue, and the mammary gland is involved only indirectly and in so far as it is embedded on all sides in this tissue."

"The frequency of interstitial changes—inflammation and sclerosis—in the mammæ of old normal mice of the material of the laboratory is striking. There is evidence that the presence of nematodes in the subcutaneous tissue may be made responsible, at least to a large extent, for such interstitial changes. In several cases these changes co-exist with typical nodular hypertrophy, and this association suggests that the different pathological changes, inflammatory processes, sclerosis and cellularity of the connective tissue, and the nodular hypertrophy of the epithelium, may be linked together and referred to a common cause, the presence of nematodes in the subcutaneous tissue."

Heterakis isolonche.

Heterakis isolonche is a parasitic nematode limited to certain species of pheasants (*Phasianus colchicus, P. reevesi, Chrysolophus amherstiæ, C. pictus, Gennæus nycthemerus*, &c.) and responsible

Fig. 46.

for a fatal nodular disease of the cæca first noticed by Klee in Germany in 1891, and by Railliet in France the year following. It has been reported since from Italy by Galli-Valerio in 1896, from England by myself in 1908, from Holland by Wassink in 1916, and from North America (United States and Canada) by Schwartz in 1924. Several other authors, such as Letulle and Marotel (1901), Lucet and Henry (1911), have described the neoplastic spindle-celled texture of the Heterakis nodule. Railliet proposed to call the disease "verrucose typhlitis"; it is now generally known by the name of nodular typhlitis.

In my first Cancer Report, I mentioned finding *Heterakis isolonche*[1] in a Manchurian Eared-Pheasant (*Crossoptilon mantchuricum*), and I gave a photomicrograph of a section through the cæcal nodules showing the structure of the new growth, which resembles that of like nodules formed by other parasitic nematodes such as *Spirocerca sanguinolenta, Physaloptera tumefaciens, Œsophagostomum apiostomum*.

In 1916 Dr. Wassink published a very interesting monograph, "Over Gezwellen bij den Fazant, veroorzaakt door een Worm," illustrated by beautiful coloured plates. Like previous authors, he described the nodules as consisting of bundles of spindle-shaped cells, some made of larger cells with oval, lightly staining nuclei, others of smaller cells with more deeply staining nuclei. Groups of large cells and groups of small cells often lying side by side, or both types of cells may be present in the same bundle. The intercellular substance is scanty in amount and difficult to detect. The new capillaries are lined by a single layer of endothelial cells. The cellular clumps are separated from one another by connective tissue and the nodule is completely encapsuled. The histological appearance of the growth is that of spindle-celled sarcoma, or of a many-celled fibroma. The neoplasm is usually confined to the cæca, but may occasionally occur in the large or small intestine. It lies under the mucosa, between mucous and muscular coats, but it may invade the muscular coat and even reach the serosa. Just like a plant gall, it is invariably associated with the presence of a parasitic larva. Metastases (without worms) are unknown.

[1] In 1908, in a paper on "The part played by Metazoan Parasites in Tropical Pathology" (Journal of Tropical Medicine, January 15, 1908, I pointed out that probably *Heterakis isolonche*, as also *Ascaris lumbricoides, Syngamus trachealis, Spirocerca sanguinolenta, Strongylus vulgaris, Œsophagostomum apiostomum*, and other helminths, did not reach their ultimate station (habitat of fully mature stage) directly by sliding down the gullet or the wind-pipe, as was generally believed at the time, but that they penetrated either skin or mucous membrane and actively migrated through the body, travelling by way of the blood-stream, or along lymph vessels or connective-tissue paths, stopping on the way, in suitable organs, for growth and development. Thus *Spirocerca sanguinolenta*, which occurs in dog, fox, wolf, and other animals, is usually found in fibromatous nodules in the œsophagus or stomach, just like *Heterakis isolonche* is found in cæcal nodules, and one might well think with Morgagni (1764), with Davaine (1860), with more recent authors that the dog's blood-red worms, in their larval stage, had bored their way through the mucosa and settled in the loose connective of the submucosa there to attain maturity, were it not that spirocerca nodules may be found also in the most diverse parts of the body such as the duodenum, the lungs, the bronchia, the trachea, the nasal cavities, the lymphatic glands and the walls of the aorta. Likewise, *Strongylus vulgaris*, in its adult stage, is found in the horse's cæcum, but its immature stages are found in the lungs, the liver, the mesenteric ganglia, and more especially in the anterior mesenteric artery where they produce

Wassink seems inclined to believe that the growth is brought about by the secretion of some chemical substance which incites cell division.

Some authors state that they have found mature worms in the cæcal nodules of pheasants infested by *Heterakis isolonche*. This is possible, because here they reach maturity, but I have found only immature worms and, as a rule, larval forms. Quite recently (1924) Schwartz has corroborated the presence of only early stage larvæ and immature forms in the nodules, while larger mature forms occur in the lumen of the cæca. He believes that the early-stage larvæ enter first the cæca and, penetrating the cæcal mucosa, encyst in the submucosa, there to grow and attain maturity. So far, experimental evidence is lacking.

Schwartz states in his paper that "Lucet and Henry re-examined the material which formed the bases of the reports of Railliet and Lucet (1892), of Letulle and Marotel (1901), and Sambon (1908), and found that the heterakids involved were not *Heterakis gallinæ*, but *Heterakis isolonche*." The inclusion of my name in this list is out of place; Lucet and Henry never examined any material of mine, neither did I ever mention finding *Heterakis gallinæ*. My specimens were diagnosed from the first as *Heterakis isolonche*, and, unlike Schwartz, I did not find any free specimens of *Heterakis gallinæ* in the cæcal cavity of the pheasants I examined, whilst, like and before Lucet and Henry, I did find sexually mature specimens of *Heterakis isolonche*.

Relying chiefly on literature, Wassink proposed the establishment of a new species under the name of *Heterakis neoplastica* for the exceptionally large specimens he had found in the cæca of gold pheasants in Holland. Dr. Baylis, to whom I handed over the heterakids kindly given me by Dr. Wassink, compared them with material in the parasitological collection of the British Museum (Natural History), and came to the conclusion that the formation of a new species was not justified, the alleged differences being due chiefly to insufficiency or inaccuracy of description by previous authors.

---

the well-known worm aneurysms first discovered by the Dutch anatomist, Fridrik Ruysh, in 1665. There can be no doubt that the blood-stream is the highway followed by a host of parasites. Indeed, in some, intra-uterine infestation has been observed. Here, in the absence of all other forms of infestment, necessarily, the young migrating parasite must have reached the placenta by way of the uterine arteries and the fœtus through the umbilical vein.

When I first suggested (JOURNAL OF TROPICAL MEDICINE, January 15, 1908) that *Ascaris* in animals and man did not develop directly in the small intestine after ingestion of the embryonated egg, but migrated through the body and sojourned in certain organs, such as the liver, before re-entering the bowel at maturity, I was laughed at. Now the researches of Stewart (1916), Yoshida (1917), Ransom, Foster, Cram, Fülleborn, Brumpt, Mosler, Lutz and others have fully confirmed my views, yet only Manson (*Brit. Med. Journ.*, 1917) remembered my researches at the Prosectorium of the London Zoological Society and stated in his review of Stewart's work, "This certainly goes a long way to prove Sambon's view that before attaining sexual maturity the parasite must enter the tissues of its human host. Sambon pointed out that the papilla or beak, a conspicuous feature in the larval ascaris, indicated that the little organism at an early stage of its existence bores its way into the tissues."

OPISTHORCHIS FELINEUS.

Among the various helminths capable of inciting cancer in man, I mentioned, in my second report (February 2, 1925), the tiny, reddish liver-fluke, *Opisthorchis felineus*, discovered in 1884, by Rivolta, in cat and dog in Italy. I recalled that, already in 1901, Askanazy had found this trematode in association with primary hepatic cancer among the fisher-folk of the Baltic coast. He described the lesions it produces: the congestion of the liver, the proliferation of the epithelium of the obstructed, dilated, bile-canaliculi, the appearance of new-formed bile capillaries, the proliferation of the connective tissue, the hypertrophy of the glands and the production of adenomatous and papillomatous formations followed by cancerous degeneration, the whole clearly determined by parasitic irritation.

Cancer of liver and gall-bladder is exceptionally common among the fishermen of the Baltic shores. What can be the cause? Dr. Rindfleisch's researches elicited the fact that the fishermen of this region are in the habit of eating raw fish, especially during their fishing cruises, hence they are heavily infested by *Opisthorchis felineus*; the biliary ducts being crammed with hundreds of the minute, lanceolate cat-flukes.

Since its discovery in Italy, *Opisthorchis felineus* has been found in France, Hungary, Roumania, Eastern Prussia, Holland, Sweden, Russia, Siberia, Japan and Tonquin, not only in the cat, but also in dog, fox, glutton and man.

The life history of *Opisthorchis felineus* has been worked out by Askanazy. The ciliated miracidium, which escapes from the operculated egg-shell, invades a fresh-water mollusc (probably *Dreissensia polymorpha*); later, having reached the cercaria stage, it leaves the mollusc and encysts in the skin and musculature of some species of cyprinoid fish, such as carp (*Cyprinus carpio*), barbel (*Barbus barbus*), roach (*Rutilus rutilus*), tench (*Tinca tinca*), bream (*Abramis brama*), or Ide (*Idus idus*). Man, cat, dog and other definitive hosts became infested by eating these fishes raw or underdone.

Verdun and Bruyant, in Tonquin, found *Opisthorchis felineus* associated with a slightly larger hepatic fluke (*Clonorchis sinensis*) of man and certain fish-eating mammals such as dog, cat, badger and marten. Kobayashi (1911) discovered that, like *Opisthorchis felineus*, *Clonorchis sinensis* also has for second intermediate hosts certain fresh-water fishes, such as *Pseudorasbora parva*, *Leucogobio güntheri*, *Acheilognathus lanceolata* and *Carassius auratus* or the "gold-fish," in the skin and flesh of which it lies in ambush. *Clonorchis sinensis* is widely spread among the coast inhabitants of China, India, Indo-China and Japan, and it is on account of this peculiar coastal distribution that, as early as 1908, Professor H. B. Ward was able to suggest fish as the probable cause of infestation.

These two liver-flukes are joined, in China and Japan, by a third trematode, *Schistosoma japonicum*, a blood-fluke which also gives rise to a grave biliary cirrhosis, long known in Japan by the name of

Katayama disease, from the district of Katayama. According to Professor Katsurada, this schistosomiasis is very common in the central provinces (Bingo, Yamanashi, Hiroshima) of Japan and even more so at Saga, in the Island of Kyushu. Now, from a totally different source, I learn that, in this very island of Kyushu, primary cancer of the liver is three times more frequent than in the rest of Japan. Is not this striking? Does not the coincidence of the greater prevalence of liver-fluke infestation with the greater prevalence of liver-cancer in the same area indicate a very probable relationship of cause and effect?

Opisthorchis felineus, *Clonorchis sinensis* and *Schistosoma japonicum* produce, every one of them, biliary cirrhosis which may well be looked upon as a "pre-cancerous" condition, since obviously it favours the development of hepatic sarcoma. In Japan, in China, in India, the connection between biliary cirrhosis and primary hepatic cancer is well known.

But that which forcibly demonstrates the cancer-inciting agency of *Opisthorchis felineus* is an observation which has all the distinctiveness of a purposely made laboratory experiment.

On the so-called "Amber Coast" of North-east Prussia, together with *Opisthorchis felineus* we find the "broad tapeworm" (*Diphyllobothrium latum*) which begins life by entering the body cavity of some fresh-water copepod such as *Cyclops strenuus* or *Diaptomus gracilis*. When the latter is swallowed by some fresh-water fish, such as pike (*Esox lucius*), burbot (*Lota lota*) or perch (*Perca fluviatilis*), the cestode larva ("plerocercoid") encysts among the various organs or the musculature of the fish, to be ingested finally by man, cat, dog or fox.

The Kurisches Haff, in East Prussia, between Königsberg and Memel, is a bay or lagoon five miles in width, cut off from the Baltic by the Kurische Nehrung, a narrow peninsula or land spit 60 miles long and 1 to 2 miles wide; made of high sand dunes (some 250 ft.) partly covered with scrub, grass-associations and trees planted, at great cost, to fix the dunes. On it are a number of fishing villages with an aggregate population of 2,300 inhabitants who still speak Kurish, a dialect of the Lettish tongue. The low and swampy mainland coast is trenched by numerous fresh-water streams which empty into the bay; the larger are the Russ, Minge, Dange, Gile, Arge and Deime. There are no streams on the peninsula. The fisher-folk inhabiting the Kurische Nehrung are exactly like those of the mainland coast in type and habits.

Primary cancer of the liver is common on the mainland coast, yet it is said to be absent from the Kurische Nehrung. How explain this difference? The inhabitants of the peninsula and those of the mainland coast are both equally infested with the broad tapeworm (*Diphyllobothrium latum*), but only those of the mainland coast harbour the liver-fluke (*Opisthorchis felineus*). Among the shifting sand dunes of the peninsula there are no streams and, therefore, no fresh-water snails. The absence of streams with fresh-water fish and molluscs, the very local habitats of the majority of fish which foster the liver-fluke and probably a greater consumption of salt-water fish explain the absence or rarity of *Opisthorchis felineus* in the inhabitants of the peninsula and, no doubt, as Herxheimer suggests, the absence of opisthorchiasis, or helminthic biliary cirrhosis, explains the absence of primary hepatic cancer.

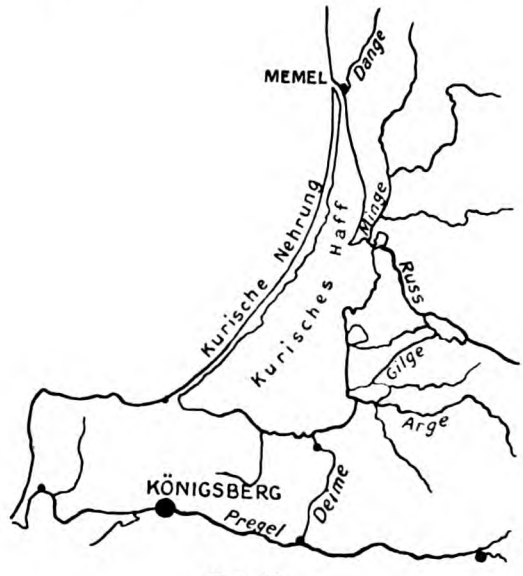

FIG. 47.

PHYTOLOGICAL RESEARCHES.

In order that I might leave nothing unattempted in the study of cancer houses and their surroundings, I sought, and fortunately secured, the expert and able co-operation of Mr. J. Ramsbottom, mycologist in the British Museum (Natural History). I was anxious to collect and determine the various kinds of fungi found in the woodwork of houses, cellars and stables and to ascertain which are the species that attract fungus-eating arthropods,[1] such as cellar beetles (*Blaps*) and wood lice

[1] We know not when man first availed himself of moulds and other minute fungi to ripen and flavour some of his cheeses, such as Roquefort, Stilton, Gorgonzola, Brie, Camembert—nor do we know when he first began to cultivate mushroom gardens in natural caves or artificial cellars, but here, certainly, he was anticipated by certain beetles (*Scolytidæ*) and by neotropical ants belonging to the myrmicine tribe Attii, who feed almost exclusively on fungi. The attiine ants grow their fungus food in subterranean chambers, on mulch beds made of leaves and flower-petals chewed to a pulp, mixed with dung and wetted with their own digestive juices. Now, without these digestive ferments, the fungus spores could hardly germinate. We have, therefore, between ant and fungus a true and strange symbiotic association, discovered by Thomas Belt in Nicaragua and ably investigated by Moeller, Tanner, Von Ihering, Dr. Goeldi and Jakob Huber. I had the opportunity of studying it in Jamaica thirteen years ago. The gardens seem to be pure cultures of a single fungus; the tiny plant is never allowed to form aerial hyphæ or fructifications, but, instead, through long domestication and selection on the part of the ant "champignonniste," it has been made to produce many rounded swellings or food-bodies (bromatia) on its hyphæ, miniature "Kohlrabi heads," as Moeller has termed them.

(*Oniscoidea*) so frequently found in stables, cellars and damp lower floors of rural dwellings.

Cancer and Dry-rot.

It is well known that the dry-rot fungus (*Merulius lacrymans*) and other hymenomycetous pests (species of *Polyporus*, *Poria*, *Coniophora*, *Fomes*, *Trichothecium*, *Rhacodium*, &c.) of woodwork in damp dwellings and cellars have long been looked upon as injurious to health and, by some (Klug and others), as causative of cancer. This alleged cancerigenous property of house fungi, however, and more especially of *Merulius lacrymans*, the true "house fungus," has been disputed by Gottschlick, Flügge, Frief, Mez and other competent mycologists.

Toadstools and Cancer.

In his report on fungus pests found in the human dwellings and stables of the Trentino, Mr. J. Ramsbottom has casually mentioned a few of the mushrooms locally used as food. In Italy, the consumption of esculent fungi, fresh or dried, is large, not only in quantities, but also in the number of species. I have seen the market-places of Trento and Bolzano ablaze with the gold-yellow of the piles of "finferli" or "galetti" (*Cantharellus cibarius*) exposed for sale. I have feasted on Cæsar's mushroom—the "uovolo" (*Amanita cæsarea*),—on "spugnola" (*Morchella deliciosa*), on "porcino" (*Boletus edulis*) and other species, all truly delicious, and shall be pleased to eat them again, even though a good lady of Trento assured me that fungus eating may give rise to cancer.

The belief that certain "toadstools" cause cancer is old and general among the peasants of the forest department of the Landes, in south-western France, where a fungus of the phalloid group, the beautiful, but malodorous "lattice stinkhorn" (*Clathrus cancellatus*) is actually called "cancer" and is avoided carefully. When found, it is usually buried beneath a thick layer of earth, lest someone should touch it inadvertently and thereby contract the dread disease. Jean Thore, a physician, of Dax, who mentions this belief in his "Essai d'un Chloris (Flora) du Département des Landes," 1803, says: "The peasants imagine, I know not why, that whosoever touches it, acquires the disease by the name of which the plant is designated." Badham, in his "Treatise on the Esculent Funguses of England," says they "call it Cancrou, or cancer."

Possibly the exceedingly offensive indoloid scent of the fungus, not unlike the putrescent odour of the fœtid "ichor" exuding from an ulcerated carcinoma, may have suggested the belief.

Clathrus cancellatus is not uncommon throughout the Mediterranean region; northwards, it extends to the Channel Islands, the Isle of Wight, Belgium and Holland. Linnæus saw it for the first time between Amsterdam and Haarlem in 1735. It has been collected at a few stations in Florida and Georgia in the United States of America.

When young and still enclosed in its volva, it looks like an egg and is so called. At maturity, the investing membrane bursts and the plant springs up, like a Jack-in-the-box, not by rapid growth but by expansion of its cells. It has a striking appearance; a red spheroidal receptacle of lattice-work composed of obliquely anastomosing bars. To the upper part of its inner surface is attached the greenish, viscid gleba, or fruiting portion, which, deliquescing, becomes excessively fœtid. The noisome odour of putrescence attracts carrion-flies needing proteolytic organisms to liquefy the flesh on which they oviposit and thus prepare their maggots' pap. By this means, so frequently used in flower-pollination, by the Aroideæ and other fly-alluring plants, *Clathrus* insures the dispersion of its spores.

The "eggs" of *Clathrus cancellatus* are eaten by Italian peasants, just as those of another species, named *Clathrus cibarius*, are used for food by the natives of New Zealand.

PLANT CANCER.

With regard to plant cancer, my investigations were limited almost entirely to the ascertainment of its presence in the districts visited.

Crown-gall is well known to the agriculturists, pomologists and wine-growers of the Trentino, who call it "gozzo" (goitre), "rogna" (scab) and "marezzo" (crispation).

The very day we reached Trento, I noticed in the garden of the Hôtel Mayer a rose-bush presenting a remarkable example of fasciation—a straight, flat, ribbon-like stem over 3 ft. high and about 2 in. broad. This striking malformation, usually brought about by the penetration of foreign organisms into the growing point, has been produced experimentally by the inoculation of *Bacterium tumefaciens* (Smith).

In Villa Lagarina, an intelligent youth of the Bolner family (which had lost three of its members from cancer) when asked about "gozzo" in plants, at once procured me a specimen from among firewood, stacked in a corner of the courtyard where we were, and told me he had seen the disease on cherry, peach, almond and grape.

At the Provincial Agricultural Institute in S. Michele, on the Adige, Signor Giglio Boni, Lecturer on fruit-growing, said crown-gall was well known in the district and occurred in the institute's nurseries. He showed me several striking specimens in the institute's museum and, later, kindly sent me a typical root-gall upon cherry.

At Trento, Commendatore G. Catoni, President of the Provincial Agricultural Council, gave me several specimens of crown-gall from apple, pear and grape with some notes on the disease which, translated into English, read as follows:—

"This disease has been known to our agriculturists for at least a century, though the specific cause remained a mystery. No great importance was attached to it at first, because its incidence was sporadic and caused little damage.

"In 1910 nursery stock was affected more frequently by crown-gall, first in the nurseries of the Upper Adige, later in those of the Trentino.

"After the war, on account of frequent complaints ıade by fruit growers, I paid special attention to this ıalady which, as a rule, after some years, leads to the eath of the infected plant.

"Nursery stock imported from Germany was made the bject of scrupulous examination and, in latter years more articularly, we noticed a recrudescence of the disease pecially in plants which reached us from Northern ermany, whence the disease seems to have been introuced.

"By means of a vigilant Custom House service we have een able to withdraw from circulation, and thereby estroy, many infected plantlets.

"The plants more frequently attacked are: Peach, ear, apple, quince and kaki, or Japan persimmon *Diospyros kaki*). The majority of tumours are found pon the roots, but overgrowths may occur on stem and imbs.

"I am now awaiting the result of investigations which re being carried out in the localities more heavily and eriodically affected, whilst myself attending to a series f experiments throughout the region in order to study he effects of the inoculation of *Bacterium tumefaciens* on arious kinds of fruit trees planted in different soils. At he present moment I am not prepared to indicate the ndemic areas, but, at the end of the inquiry, I trust I nay be able to map out the more heavily infected centres vithin the region.

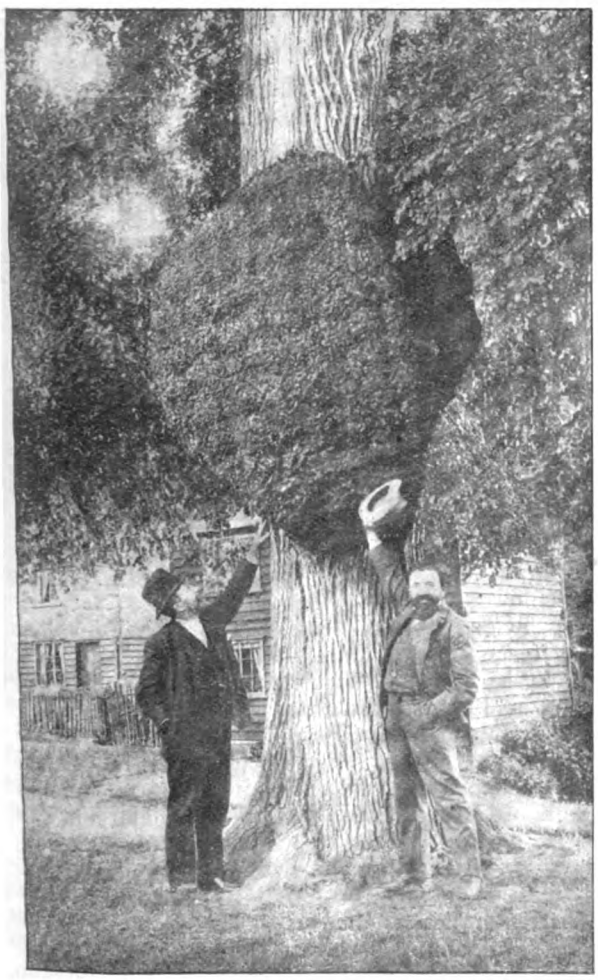

FIG. 48.—Sir James Cantlie and Surgeon-General Rho, Italian Navy, examining an enormous growth on elm tree at Buntingford. (Photograph by Dr. Sambon, taken in 1899.)

FIG. 49.—Crown gall on apple tree.

"Meanwhile, I believe I can assert that the injury caused by *Bacterium tumefaciens* is steadily increasing from year to year.

"Information received from other Italian regions also shows that considerable importance is ascribed to the damage caused by *Bacterium tumefaciens*. This organism, according to experts, is exhibiting a decidedly infectious character.

"With regard to remedies, there is, so far, nothing sure, nothing positive."

In Milan, at the superb Serotherapeutic Institute, directed by Professor Belfanti, we were shown a number of tomato plantlets which had been inoculated with pure cultures of *Bacterium tumefaciens* and presented the characteristic swellings.

In the Province of Rome, on my way from Sambuci to Saracinesco, while climbing the steep mule-path that leads to the old Saracenic fortress, I noticed that the hedging brambles were tumoured. Some of the swellings were large pithy galls produced by a gall-wasp, others, along the stem, were characteristic of crown-gall, a disease which frequently affects the blackberry, as also its close relative the raspberry, though the overgrowths on the latter usually are smaller and confined to the crown and roots.

Two main cultures clothe the fertile valleys of Tridentine Venetia: grape and pomaceous fruits. Viticulture was by far the more extensive in the past, but, within the last half century, the cultivation of pomaceous and drupaceous fruit trees has increased greatly and is now displacing the bacchic vine. The chief fruit-culture is that of the apple, in several excellent varieties, then follow pear, peach, apricot, cherry, walnut and chestnut. All

these and the grape-vine are more or less susceptible to crown-gall. I have seen the disease, in its "gall," "broom" and "hairy-root" forms, on rose, pear, apple, cherry and grape. I have seen it also, whitish, translucent, almost opaline, on a geranium (*Pelargonium*) in a flower-pot at the window of a house in Lavis. That crown-gall is a serious disease of the grape-vine in Northern Italy is a fact long known, and, indeed, it is to the study of the "rogna" or "tuberculosi" of the grape in Italy that we owe our knowledge of the disease.

Travelling through Holland and Italy one is impressed by the frequency of woody knarls and warty overgrowths on trees, especially when the latter are planted in close rank along the interminable country roads and canals. Some of these overgrowths, on collar, stem or limb of poplar, elm, chestnut or willow, doubtless are true plant-cancer. All, whether burrs, cankers, wood-nodules or witch's-brooms, so far as we know their cause, are the outcome of parasitism.

Dr. Erwin F. Smith's remarkable investigations and Dr. Ferdinand Blumenthal's recent experiments have focused attention on crown-gall and, no doubt, more may be expected from their researches.

Crown-gall (crown-knot, limb-gall, root-gall, hairy-root, woolly-root or plant-cancer) is a disease of world-wide distribution remarkable for the large number of plant families subject to its ravages. Among some of the best-known host-plants are: tobacco and many food-plants such as potato, cabbage, cauliflower, tomato, turnip, carrot, sugar-beet, red-beet, radish and lettuce, hop, clover and medic, blackberry, raspberry, grape, cherry, plum, peach, apricot, pear, apple, quince, almond, chestnut, walnut and avocado. Numerous floral and ornamental plants are subject to its attacks, I need but mention the rose, carnation, geranium, chrysanthemum, honeysuckle, sunflower, oleander, poplar and willow.

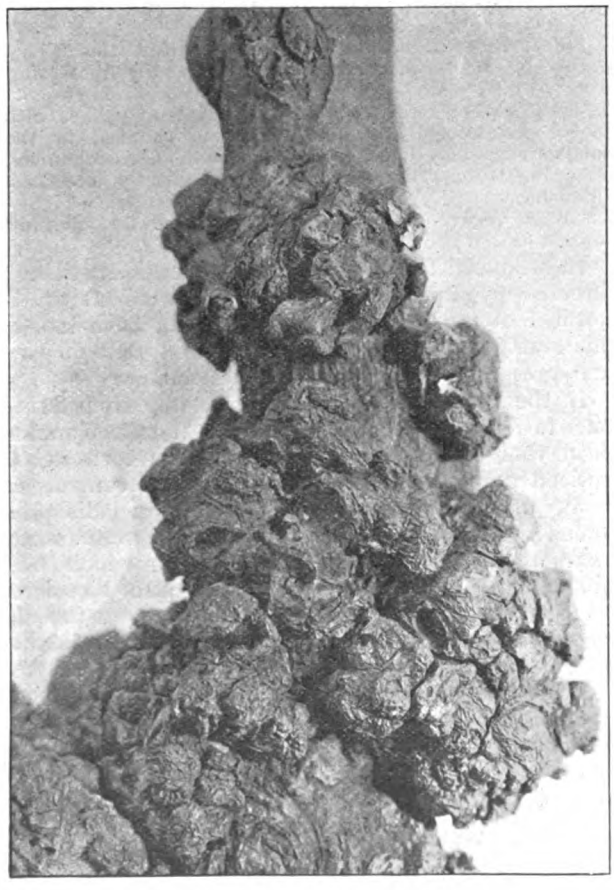

FIG. 50.—Crown gall on pear tree.

FIG. 51.—Crown gall on grape-vine.

For obvious reasons, crown-gall is more prevalent and better known in cultivated than in wild plants, just as animal-cancer is more prevalent and better known in domesticated than in wild animals.

Whilst in some plants the disease more commonly affects the "crown" (that part where root and stem meet) or the roots, often giving rise to bunches or tufts of closely matted rootlets with enlargements at their base (hairy-root), in others (quince, poplar) it produces gall-like swellings on various portions of the limbs and twigs, often covering an entire limb with irregular warty outgrowths.

The malignancy of crown-gall in plants varies considerably. As a rule, it is greater in Dicotyledons than in Monocotyledons. In many woody trees it does not seem to cause much injury. Thus, in pear, apple and cherry, its action is usually slow.

ır well-rooted trees may outgrow the disease in a ear or so, but there are varieties of apple in which appears to be very destructive. Grape, peach, mond, raspberry, rose and willow are seriously jured and frequently killed. Other plants, such olive, onion and garlic, seem to be immune.

In susceptible species the amount of damage deends greatly on the age of the plant and on the cation of the new growth. Young plants are more riously injured and may be killed by a terminal id inoculation. In severe attacks the affected ants become stunted and sickly, their leaves

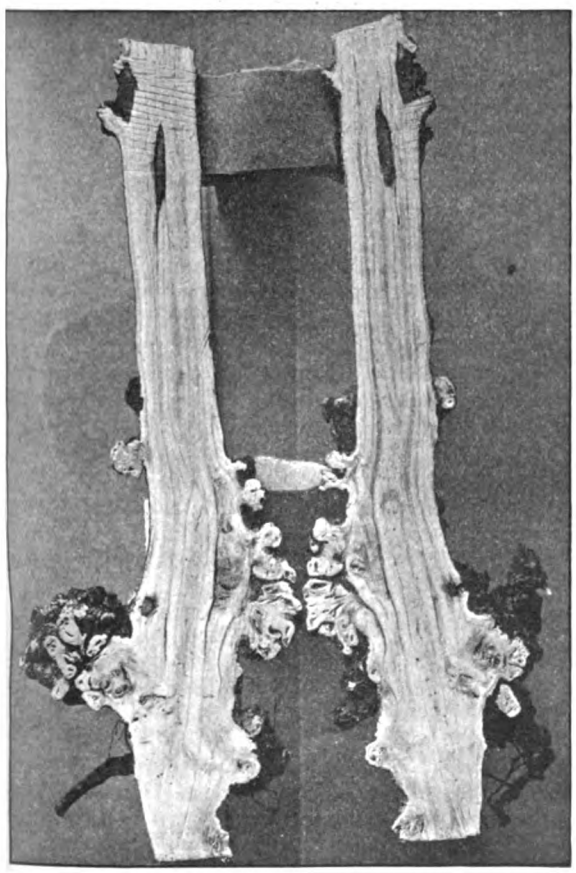

FIG. 52.—Longitudinal section of pear-tree stem with crown-gall, showing tumour-strand.

mall and chlorotic (yellow), while unfruitfulness as been noted.

It was Dr. Erwin F. Smith, doyen of American lant pathologists, who, in 1909, first pointed out he striking resemblance existing between the rown-gall of plants and malignant animal tumours.

Like cancer in man, so the plant overgrowth egins with frenzied hyperplasia. Its cells proiferate in an abnormal manner, dividing hastily, epeatedly, immaturely and with extraordinary apidity; they become small, atypical, disoriented, xhibiting a strong affinity for stains. Their reatly reduced cytoplasm contains numerous coarse ranules. On account of incomplete development, he tumour-cells assume an embryonic appearance; they divide mitotically or amitotically and their nuclei may be lobed or cleft; often several nuclear fragments are seen in one cell.

The rapidly multiplying cells foam up, as it were, into a mass of non-capsulated, small-celled neoplastic tissue supported by a variable amount of stroma and of twisted, distorted, thin-walled vessels (tracheids and sieve tubes corresponding roughly to blood-vessels and lymph channels) developed out of the surrounding normal tissues.

As the tumour grows, it destroys contiguous tissues by compression or infiltration, but, finally, being subject to early decay, on account of imperfect vascularization, it is in turn destroyed by a variety of disintegrating bacteria and fungi.

The structure of the neoplasm varies according to the tissue primarily affected. The majority of tumours are made up of the ordinary ground or parenchymatous-cells (cortex, pith, medullary-ray-cells) and may well be compared to the connective-tissue growths or sarcomata of animals; others, being composed mainly of epidermal elements, parallel the epitheliomata; others again, containing teratoid elements in addition to cancerous cells, are fully comparable to the atypical teratoid tumours of man and animals.

Embryonal teratomata in crown-gall were first observed by Smith in 1916 in shoots of red-flowered pelargoniums and since repeatedly obtained in a great variety of plants (*Citrus*, *Lycopersicum*, *Okra*, *Brassica*, *Beta*, *Nicotiana*, *Ricinus*, *Opuntia*, *Rosa*, *Fuchsia*, *Hibiscus*, *Allamanda*, &c.) by stimulating proliferation either in the leaf axils wherein lie dormant buds, or in toti-potent cells capable of reproducing shoots.

In the "wonder plant" (*Bryophyllum pinnatum*), called "life-plant" in the Island of Barbados, where I first saw it, adventitious plantlets invariably develop in a normal way from the marginal indentations of its leaves, whenever the latter are torn off the stem. The Barbadians suspend fragments of the leaf by a thread to watch the "wonder." These leaf-plantlets eventually grow into normal plants, but in crown-gall we witness a strange awakening of toti-potent cells induced by a pathogenic stimulation, and the shoots, buds and roots which arise, form, as a rule, a jumbled mass of incomplete, distorted structures which soon perish.

The most striking feature of crown-gall, the feature which certainly likens plant-cancer to animal-cancer, is the development of secondary tumours from the primary neoplasm invariably reproducing the structure of the mother tumour, no matter where arising. These secondary tumours are lateral offshoots from a tumour-strand, a continuous chain of proliferating tumour-cells exactly like the chain of cancer-cells which in animals spread along the lymphatics by a process of continuous forward growth. Mr. Sampson Handley has termed it "permeation" and proclaimed it to be the "master process of cancer dissemination." These parenchymatic tumour-strands in plants are sometimes large enough to be clearly visible to the naked eye in both

cross and longitudinal sections, but more often consist of a thread of cells so delicate that it is difficult to recognize them, even under the microscope.

Nothing could have seemed stranger, more puzzling, than to find in secondary tumours the characteristic elements of the tissues in which the primary growths arose, such as bone in brain tumours, the bright yellow secretion of bile in lung metastasis, lignin (wood) and the concentric closed structure of a stem, or again " root-structure " in leaf-galls, yet nothing is easier to understand when one remembers that secondary tumours arise either in direct continuity with the primary growth by means of tumour-strands, or from detached portions of proliferating tumour-cells carried through the vascular system to another part of the host's economy and there ingrafted.

The initial tumour in every instance, so far as we know, appears in a wound caused either by sunscald, the battering of hailstones, agricultural implements or the gnawing, puncturing, boring of rodents, insects or nematodes.

The size of the overgrowth may vary from one to several inches in diameter. At first it is small, relatively smooth and soft, whitish, greenish or slightly roseate, almost translucent; later it increases in size, becomes hard, warty and browned. As in animal-cancer, so also in plant cancer, the youngest growing part of the tumour is at the periphery, while the oldest, decaying, necrotic part is central.

In plant-cancer, as in animal-cancer, the disease recurs after excision or cauterization, unless the whole of the morbid growth is removed. Sometimes crown-gall recedes of its own accord just as cancer may disappear, for unknown reasons, in animals and man. Finally, like malignant tumours in animals, plant-cancer can be grafted on to other plants of the same species.

The parasitic nature of crown-gall had been suspected long ago, indeed, experiments by numerous investigators had proved that the disease is communicable, because infection of susceptible plants was obtained by planting young trees in the vicinity of diseased ones, by burying fragments of galls in contact with the roots of sound trees, by grafting and by inoculation with macerated galls. Bacteria were incriminated by Corvo in 1885, by Cuboni in 1889, by Comes in 1892; other phytopathologists suggested fungi. As late as 1900 we found Professor Toumey suspecting a myxomycete which he names *Dendrophagus globosus*.

The credit of having demonstrated the bacterial nature of the disease, by means of inoculations from pure cultures, belongs to F. Cavara, Professor of Botany in the Royal University of Naples.

" Although Cavara's account is meagre," says Dr. Erwin Smith, " there is little doubt in the light of our own experiments that he had the right organism and reproduced the disease with it as he says he did. His experiments, however, were so few in number that they did not convince anyone and were generally overlooked."

Cavara studied crown-gall in the grape-vine from material obtained near Venice. He published a preliminary note in 1895, a fuller paper in 1897 and a third one in 1890. As first pointed out by him, the gall-forming bacterium occurs in small numbers scattered through sound-looking tissues and is very difficult to see when stained. He says:—

" I cultivated the bacterium in gelatine prepared with green shoots of the vine, and the Petri dish poured plates gave circular, flat colonies of nacreous hues, which did not liquefy the surrounding gelatine. . . . With cultural material many times renewed by transfer, I made inoculations in the Botanic Garden of Pavia. T-shaped incisions, after careful sterilization, were inoculated either in the lower internodes of shoots of the year, or in the upper internodes, while as many were simply incised without inoculation of the virus for purpose of control. Of two European grape-vines, one was inoculated in four of its branches, the other merely incised for control. All of the four inoculated branches produced overgrowths, not of large dimensions, it is true (1 to 1·5 cm. in diameter), but of the same form and structure as those on the Udine vines."

In 1907, Smith and Townsend published the results of their researches on crown-gall made in the cultivated marguerite, or Paris daisy (*Chrysanthemum frutescens*). Like Cavara, using sub-cultures descended from agar-poured-plate colonies, they introduced this organism by means of needle pricks into healthy daisies and other plants (tobacco, potato, tomato, sugar-beet and peach) and, under favourable conditions (young tissues), succeeded in reproducing characteristic tumours in 100 per cent. of infections. From these experimentally obtained overgrowths the inoculated organism was recovered, cultivated and again successfully used to reproduce the disease. Control plants remained invariably healthy while punctures made with sterile needles never gave rise to overgrowths.

" I insert my infected needle," says Dr. Smith, " and I obtain a tumour. I insert a sterile needle and the wound heals normally. Into one branch of a young Paris daisy I set my infected needle fifty times and obtained fifty tumours; at the same time into the twin branch I set a sterile needle fifty times and obtained no tumours whatsoever, but only a normal healing of the wounds."

Smith and Townsend proposed the name of *Bacterium tumefaciens* for the crown-gall organism. Its morphological and cultural characters are as follows:—

Bacterium tumefaciens is a short rod with rounded ends, motile by 1-3 polar flagella; measures 1·2 to 2·5 microns by 0·5 to 0·8 microns; neither spores nor capsules demonstrated; pseudo-zoöglœæ occur; involution forms present; stains with the usual aniline stains; Gram-negative; on agar, slow, four to six days at 25°; filiform, raised, white, glistening, somewhat slimy; potato, growth rapid, white, smooth, wet-glistening; gelatine stab, filiform, no liquefaction; blood serum, moderate; broth, ring or pellicle, clouding absent or inconspicuous; milk, coagulation delayed, curd not peptonized, litmus gradually blued, then reduced; silicate jelly, slow white growth; Cohn's solution, scanty or absent; Uschinsky's solution, scanty, not viscid; NaCl bouillon, 4 per cent. inhibits, 3 per cent. retards; bouillon over chloroform, growth unrestrained, no gas from sugars; ammonia is produced; nitrates not reduced; indol production small; thermal death-point 51°, optimum reaction between — 14 and — 24 Fuller's scale, opt. temp. 25° to 28°, max. 37°, min. positive at 0°; killed readily by drying; moderately sensitive to sunlight, invertase and rennet thought to be produced.

From the first, when together with his associates, Dr. Erwin Smith isolated *Bacterium tumefaciens* from crown-gall overgrowths, he thought that the same, or a very similar organism, might be the inciting agent of cancer in animals and man. At that time, when pathologists denied the parasitic nature of cancer in man and animals, when many phytopathologists denied the very existence of bacterial diseases in plants, the suggestion of a schizomycete causative of cancer in man, animals and plants must have seemed preposterous. Yet Smith inoculated *Bacterium tumefaciens* in brook-trout (*Salmo irrideus*) and other cold-blooded animals, persevering in spite of obstacles and failures.

In a paper on "Cancer in Plants," read before the Seventeenth International Congress of Medicine, held in London, August 1913, Dr. Smith said:—

"I have obtained indications, at least, in fish inoculated with this organism, of overgrowths which seem to me suggestive of sarcoma. I will not say much here about animal inoculations, because I am not so sure of my ground and, further, because I have not obtained large and striking growths of the inoculated animals, such as I did in my control plants. In fact, I was so much discouraged with the result of my first inoculations on brook trout made now five years ago, that I contented myself with simply fixing the material, and did not have any sections cut from it for nearly two years. It then occurred to me that while I had not obtained striking growths in the fish, the sections might give some helpful indications. Sections were, therefore, cut from a number of inoculated fish, and while many of them showed what I took to be inflammation only, others gave indications of what seemed to me to be the beginnings of sarcoma. I was interested enough in the matter to repeat the experiment in 1912-13, and again obtained what I take to be substitution of connective tissue cells for muscle-fibre in various inoculated fish, but, again, no well-developed tumours, only small nodules."

The trout, inoculated by Dr. Smith with cultures of *Bacterium tumefaciens* in the eye-socket, developed several times small nodular growths in the eye-muscles and elsewhere, but died before it could be determined whether these growths were really malignant neoplasms. Usually the inoculated fish died of septicæmia due to the inoculated bacteria. In one instance a practically pure culture of *Bacterium tumefaciens* was plated from the dorsal aorta of an inoculated trout and crown-gall was reproduced in sugar-beets with subcultures from its colonies.

In 1915, Friedman, Bendix, Hassal and Magnus claimed to have discovered *Bacterium tumefaciens* in man, associated with various morbid conditions such as intestinal ulcerations, purulent meningitis and synovitis. By means of this organism, isolated from human fæces, they were able to produce typical, rapidly-growing tumours in plants (*Pelargonium*).

Quite recently (1925), Professor Ferdinand Blumenthal, Director of the Cancer Laboratories of the great Charity Hospital, in Berlin, and his assistants, Dr. Hans Auler and Fraulein Paula Meyer, have claimed the discovery of *Bacterium tumefaciens* in human cancer. On examining the juice extracted from a breast carcinoma, Paula Meyer found a rod-shaped organism which proved to be *Bacterium tumefaciens*, not only on account of its morphological and cultural characters, but also because, inoculated into sun-flower plants, it gave rise to typical crown-gall overgrowths.

In consequence of this unexpected finding, thirty malignant neoplasms of various kinds (sarcoma, carcinoma) were examined and *Bacterium tumefaciens*, or some (one or several) closely related organisms, found in twelve of them (8 carcinomas, 2 sarcomas, 2 cancroids). Pure cultures, when obtainable, were inoculated into laboratory rats, mice and guinea-pigs; they gave rise to new growths which attained the size of a small pea, then receded; they could not be grafted. Further inoculations of the organism, mixed with sterile diatomaceous earth, as an irritant, and with lymph from the "brawny arm" of a patient suffering from breast-carcinoma, yielded more definite results; the new growths reached the size of beans in mice and rats, that of small cherries in guinea-pigs; they proved more persistent, formed metastases and were transplantable. Histologically, the inoculation growths were, for the most part, mixed tumours, but the transplants resembled more and more the well known sarcomas and carcinomas of mice and rats.

The said bacteria were only found at the periphery of soft, opened human tumours, never in hard, closed ones; they could not be demonstrated in the new growths experimentally produced by inoculation, and were never found either in metastases or transplants.

Since *Bacterium tumefaciens* has been found in association with metastasizing tumours, not only in the most diverse plants, but also in animals and man, it becomes imperative that we should understand the nature of the association and the mode of action of the bacterium, if any, in producing overgrowths.

In the first place, we should know the exact location of the organism within the tumour tissues. Unfortunately opinion varies considerably on this point. Cavara (1897) found the specific organism scattered through the vessels and tissues of the cortex in the smaller and younger growths. "They do not form distinct foci," says he, "but are found scattered here and there in the various tissues."

Recently (1923) A. J. Riker made an effort to locate the organism in the tissues He studied crown-gall in the tomato plant, examined the tissues at different stages of gall-formation and scrutinized the secondary as well as primary growths. "The evidence," he says, "seemed to indicate that the organism was living between the cells of the host. Its intercellular position and its scarcity apparently contributed to the difficulty of demonstrating it in the tissues. Under certain conditions the organism was found to travel through the vascular bundle. This resembles a method of distribution of cancer in animals."

Wilfrid Robinson and H. Walkdern, in "A Critical Study of Crown-gall" (1923), state that they were "able to demonstrate conclusively zoogloea strands of *Bacterium tumefaciens* along intercellular spaces and protoxylem vessels forming

centres for pathological disturbance and gall production along the tract."

Dr. Erwin F. Smith, on the other hand, has repeatedly asserted that the bacterium is not found either in vessels or intercellular spaces, and therefore must lie concealed within the granular, deep-staining cytoplasm of the tumour cells; there are no indications of its presence inside the nucleus.

In 1913, he says:—

"One of the most difficult features of the investigation has been the demonstration of the micro-organism in the tumour tissues by means of stains. For many years we have known that it was present there, because we could isolate it therefrom by the poured-plate method, but when we undertook to stain it in the tissues we discovered that it would not stain by Gram, that it was not acid-fast, and that when it did stain the protoplasm of the cell also stained, and such numerous and various granules appeared in the microscopic picture that we could not be certain whether the few rod-shaped bodies which we saw within the cells were actually bacteria or only normal constituents or degenerations of the cell contents. Very many attempts were made to counterstain the organism, so that we could differentiate it sharply. We knew that it must be within the cells, because the intercellular spaces are free not only from bacteria, but from granules of any sort, and also because the vessels are free. Assuming it to be of a size within the limits of microscopic vision, and its size on culture media seems to point to that conclusion, the only place where it could be was inside the cell. A great variety of aniline stains and various preliminary methods of fixing the tissues were tried without success. . . . Finally, I decided to abandon the aniline stains and try other methods, using salts of the heavy metals. We first tried impregnation with nitrate of silver, but without satisfactory results. Finally, however, with gold chloride, we obtained clear pictures of the micro-organism inside of the cells. . . . By this method they have been demonstrated beyond question within certain of the tumour cells and have been photographed. . . .

"It turns out that the organism is not very abundant in the cells, and is restricted, it would seem, to a small proportion of the total number of the cells forming the tumour. Its morphology within the cell is essentially that of the same organism grown in pure cultures under somewhat abnormal conditions, that is, under such conditions as lead, in tube cultures or flask cultures, to the production of club-shaped and Y-shaped or branched involution forms."

Three years later (April, 1916) he writes:—

"I cannot now say unqualifiedly that I have ever seen the organism within the cells. At times I have thought so, but I am now again in doubt. I have seen under very high powers of the microscope in fresh sections occasional rod-shaped bodies moving slowly within the cells. All attempts at differential staining by means of aniline dyes have failed, in spite of repeated trials. Subsequently, by means of gold chloride, we stained within certain of the tumour cells rod-shaped bodies which I interpreted, perhaps prematurely, as the bacteria. They agree in form and even show branching rods, but nevertheless may be normal organs of the cell. For the present then we have to depend on culture methods and on diffusion methods for demonstration of the presence of the bacteria in the tumours."

Club-shaped, Y-shaped and variously branched involution forms, similar to the bacteroids of the root-nodule bacteria of legumes, can be produced at will in cultures of *Bacterium tumefaciens* by subjecting them to unfavourable conditions such as cold, excess of sodium chloride, the action of a dilute acid or of an assimilable sugar. Poured-plates made from cultures so treated show that the majority of the organisms are dead, while the remainder are in a torpid, benumbed condition and, therefore, develop slowly in plates, just as they ordinarily do when taken directly from the tumours.

"It took us, I am ashamed to admit, about two years," says Dr. Smith, "to learn that if we would obtain cultures of *Bacterium tumefaciens* on agar-poured plates, we must not only inoculate heavily, but we must wait for a period of more than four days. Usually it requires five to seven days, sometimes ten days, and occasionally fifteen to twenty days for the benumbed organism to recover its normal morphology and vigour and develop in the form of colonies. . . . Since these facts were brought into clear light, it has been easy for us to obtain the organism from young tumours and to reproduce the disease in plants . . . That there is a numbing of the bacterium in the plant, which proceeds as far as death in many instances, is shown by the fact that at no given period are there any great number of living organisms in a given bit of tissue, and often in old tissues none whatever, as demonstrated by the poured-plate method."

Dr. Smith is inclined to give considerable importance to these involution forms in the genesis of the tumour.

"My hypothesis of the tumour-development," says he "is as follows: The micro-organism entering the cells as the result of slight wounds grows rapidly for a time. Its growth is then inhibited, apparently by its own by-products, of which one is an acid (at least in flask cultures). As the result of this inhibition many of the bacterial rods swell, becoming clumpy and variously branched, giving rise to the so-called Y-bodies. There then ensues death for many, and a dormant period for the remainder. The organisms which are killed outright, by the by-products evolved during their previous growth in the cell, are the ones which now stimulate the nucleus to development. This I conceive to take place by endotoxins or other substances, which can now pass readily through the dead walls of the bacteria and into the cell cavity to stimulate the nucleus. As soon as the nucleus begins to divide, its membrane disappears, and its contents (presumably alkaline) flow into the cell. As the result of this nuclear contents pouring into the cell, and commingling with the benumbed bacteria, they take on a new growth, pass over into the daughter-cells, and there grow rapidly for a short time, whereupon they are again inhibited with the production of the aforesaid involution forms. The nucleus in the daughter-cells now divides, and the process is repeated indefinitely."

With the help of the expert chemists (Alsberg, Brewster and Woodward) of the United States Department of Agriculture, Dr. Smith endeavoured to determine what chemical substance, resulting from the metabolism of *Bacterium tumefaciens*, might be the direct exciting cause of the abnormal cell-proliferation in crown-gall. Flask cultures were prepared with different strains of *Bacterium tumefaciens* (from Paris daisy, hop, rose, poplar) inoculated on a simple culture medium made of substances (water, peptone, grape sugar and calcium carbonate) approximating those naturally occurring in plant cells. Other flasks, containing the same medium, were held uninoculated for control. Before turning the flasks over to the chemist, Petri-dish agar plates were poured from each inoculated flask to ascertain whether the cultures continued pure, then subcultures from each were inoculated into susceptible plants to determine whether they were still pathogenic. Thus various flasks were tested and

worked up separately, with, in the main, concordant results.

The chemical analyses disclosed the following bacterial products: ammonia, amines, aldehyde, alcohol, acetone, acetic and formic acids, to which Smith adds, inferentially, carbonic acid. All of them are substances which pass readily through protoplasmic membranes, and Smith points out that the majority are "just those compounds found by Loeb and others to be most efficient in starting the development of unfertilized sea-urchins' eggs," a fact "not only astonishing, but extremely suggestive."

Experimenting with each one of these substances (first water dilutions painted on or injected, later their vapours) on several plants subject to crown-gall (ricinus, cauliflower, tomato), but in the absence of bacteria, Dr. Smith obtained decided overgrowths which he looks upon as "incipient crown-gall."

"The overgrowths are small," he says, "as was to be expected from the application of a single slight stimulus. They do not continue to grow because they are the response to an abnormal outside influence of very limited duration, or, to put it in another way, because there is no parasitic organism back of the growth, as in the case of the natural crown-gall, continually to stimulate it by means of its excretions.

"These tumours are either vascularized hyperplasias, mixed hypertrophy and hyperplasia, or simple hypertrophies. In them the cells are much more closely compacted than the parent cells and free from chlorophyll. The cells of the hypertrophies are frequently a hundred times the volume of the cells from which they have originated. In the acetic alcohol tumours there has been a great increase in the number of the cells, i.e., the development of a true hyperplasia, while in the hypertrophies the component cells appear to be the original cells greatly enlarged.

"Curious vascular displacements and duplications have also been obtained, including, in one instance, an entire extra vascular cylinder in the pith of ricinus."

Further experiments with various salts of ammonia, with dilutions of their acid compounds and with various foods and poisons also yielded similar growths.

In detailing these experiments in a paper on "Mechanism of Tumour Growth in Crown-gall," published in the *Journal of Agricultural Research*, Washington, January, 1917, Dr. Smith expresses his views on the causation of crown-gall. He says:—

"The ultimate cause of cell proliferation in crown-gall is the schizomycete *Bacterium tumefaciens* Sm. and T., but the mere mechanical irritation due to the presence of a few rod-shaped bacteria in the tissues cannot be the direct cause of the proliferation, since other species of bacteria either have no specific action when inoculated into plants or some quite different action. . . . The immediate or proximate cause of the abnormal proliferation must be the chemical or physical action of enzymes or other substances produced or activated by the bacteria as a result of their metabolism, with a corresponding reaction on the part of the plant. . . .

"At first I conceived of the crown-gall phenomenon as much more complex than it really is. I thought of endotoxins and other complex substances of unknown chemical structure as probably the cause of the excessive cell proliferation, not, however, entirely excluding simpler substances, such as ammonia compounds. . . .

"In the beginning I had what I now believe to be a wrong conception of growth. I looked upon it as something that an outside substance could directly stimulate into development, but probably it is not that (Weigert, Ribbert, Loeb). Growth is the normal function of cells. They are always multiplying when they are not inhibited by one thing or another; growth, then, if this view is correct, comes about not by the direct application of stimuli, but indirectly *by the removal of various inhibitions*. . . .

"As I now see it, tumour growth is not at all a chemical phenomenon, but rather a purely physical one, a matter of varying molecular vibrations, a development dependent on locally increased osmotic pressures which cause a movement of water and foodstuffs into the affected area. In crown-galls the removal of growth inhibitions is brought about, I think, by the physical action of substances liberated within the tumour cells as the result of the metabolism of the imprisoned bacteria. . . .

"If the cell proliferation in crown-gall is due to substances liberated within the cell by the parasite, as it seems reasonable to suppose, they must be substances either identical with or at least not differing greatly in their physical or physiological action from those acting on the non-parasitized cell during normal growth and division. Of this there can be little doubt for several reasons, and especially for the reason that there is no evidence of chemical injury either in the tissues surrounding a crown-gall or in the tumour cells themselves, since they grow and multiply with a rapidity only to be compared with that of the cells of normal young tissues. This at once removes from consideration all actively poisonous (killing) substances and greatly simplifies the problem. . .

"On the start, it seemed to me probable that ammonia given off in small quantities within the cell by the multiplying bacteria must be the sole determining factor in the abnormal cell proliferation, since as a diffusible stimulant it would enter cells readily, would increase the osmotic pressure, and would tend to enter into soapy combinations with the lipoids of the cell surface, thus changing the surface tension beyond the point of physiological cell restraint, whereupon cell division would take place. . . .

"Consequently, without entering into further details, I will say that I think I have established my original hypothesis—viz., that dilute ammonia causes intumescences and renders it probable that ammonia, liberated within the cell in small quantities by the imprisoned bacteria, must be one of the causes of the excessive and abnormal cell proliferation in crown-gall. Probably amin compounds also help to determine it. Since an acid and an alcohol are likewise produced by the crown-gall bacteria, and this alcohol and this acid (as well as many other acids) in pure dilution and also in combination with ammonia caused galls or intumescences in my experiments, the acid (or acids), the alkalies, and the alcohol must, I believe, act together in producing the tumours, and *osmotically rather than chemically*.

"To conclude, it would seem, therefore, that in local osmotic action (possibly in some stages chemical action also) of various substances (aldehyde, acetone, alcohol, acids, alkalies) thrown into cells and diffusing from them in various directions, as the result of the metabolism of a feeble intracellular parasite or symbiont, together with the resultant counter movements of water and food supply, we have, in crown-gall at least, and presumptively also in animal neoplasms, the explanation of tumour growth—that is, of that extensive multiplication of cells in opposition to physiological control which has so long puzzled pathologists and all students of overgrowths."

Whatever may be the ultimate result of the investigations on crown-gall made at the Bureau of Plant Industry, U.S. Department of Agriculture, by Dr. Erwin F. Smith and his colleagues (Brown, Townsend and McCulloch), certainly they have advanced knowledge in plant pathology and have

brought to the elucidation of the cancer problem a most valuable contribution.

Dr. Smith was the first to call attention to the striking similarity existing between crown-gall and malignant animal tumours; together with Townsend he confirmed and extended Cavara's findings, isolated the incriminated schizomycete from overgrowths in the most diverse plants and gave it the name of *Bacterium tumefaciens*. He pointed out that this organism could give rise in plants to neoplasms comparable to the various forms of cancer known in man, from a plain connective tissue hyperplasia (sarcoma) to a solid embryoma, the differences between the various types of tumours being due to unlike reactions of the different tissues. He showed that the plant overgrowths give rise to secondary tumours, usually repeating the structure of the mother tumours from which they arise by permeation in the form of long strands of infected cells. Finally, suspecting the sameness of cancer in plants, animals and man, he started experiments by inoculating the crown-gall organism in cold-blooded animals and succeeded in obtaining the formation of suggestive growths in brook trout.

The experimental production of teratomata by the inoculation of *Bacterium tumefaciens* in the leaves and internodes of susceptible plants certainly is an achievement of considerable oncological and biological interest.

Oncologically it is of importance:—

(1) Because, as Dr. Smith has shown, teratoid tumours in plants are made up of cancer cells dragging with them in their crazy proliferation, fragments of leafy shoots, abortive roots and flower buds stimulated into being, twisted, broken, jumbled, engulfed.

(2) Because these plant teratoids, being essentially like the so-called "atypical teratomata" of animals and man, suggest for the latter a like origin.

(3) Because they deal a deadly blow to Cohnheim's theory of embryonic remains since, by means of infected needle-pricks, teratoid tumours may be obtained from ordinary meristem cells in the middle of young leaves where no dormant buds are known to exist. "Seven teratoid tumours obtained from the blade of a single leaf, twenty-seven from the leaves of a single plant, surely are too many to be due to dislocated 'cell-rests'!"

Biologically it is no less important, because it contradicts Weismann's speculative theory of germ-plasm and somatic or body-plasm, and shows that young somatic cells in any part of the body may produce all of the organs and tissues of the entire plant including germ-plasm. Obviously, either each body-cell has retained its potential quota of hereditary characters or portions of the germ-plasm are widely distributed through the tissues of the plant. That a similar capacity for regeneration exists also in some degree in the somatic cells of animals has been known since Abraham Trembley made his experiments with Hydra in 1741.

Fully recognizing the importance of Dr. Erwin Smith's work on crown-gall, I must say that I do not believe *Bacterium tumefaciens* to be the essential cause of plant cancer, though, certainly, it appears to be an important factor in bringing about the overgrowth.

In the first place, *Bacterium tumefaciens* is not an endocellular organism, as, necessarily, it would be, if it were the cancer parasite. At one time, Smith did think that "it must lie concealed within the cytoplasm of the tumour-cells," because he had failed to detect it in the intercellular spaces and vessels. Indeed, he thought he had succeeded in staining it with gold chloride and even stated that he had photographed it within its cell-host, but he soon recognized and acknowledged his error, pointing out that the few rod-shaped structures he had mistaken for bacteria were probably degeneration products of the cell contents or mitochondria.[1]

Recent investigations have confirmed Cavara's early observations and we know that, as stated by him, the organism is "scattered through the various tissues and vessels, in the smaller and younger growths." Yet it is difficult to detect on account of its scarcity, its intercellular position and the fact that it is not found in the interior, but only at the periphery of young tumours. Already Virchow had shown that, in human cancer, the periphery is the youngest part of the growth and taught that one must study the outer parts of tumours to understand their development. Moreover, he had said: "A pathological tumour in man forms in exactly the same way as does a swelling on a tree, whether on the bark, on the surface of the trunk or on a leaf, wherever any pathogenic irritation has occurred.

In the tumour tissues, according to Smith, "*Bacterium tumefaciens* occurs only in small numbers in a live and cultivable state" and the surviving organisms are "in a torpid, benumbed condition, so that they will not immediately grow upon transfer to culture media." They are swollen, variously branched, many club-shaped or Y-shaped, just like the involution forms of the root-nodule bacteria. A few dying bacteria hardly seem capable of producing that sudden, rapid and intense hyperplasia which is characteristic of malignant neoplasms. Indeed, Smith himself admits that "the mere mechanical irritation, due to the presence of a few rod-shaped bacteria in the tissue, cannot be the direct cause of proliferation since other species of bacteria either have no specific action when inoculated into plants, or some quite different action." He argues, therefore, that the cause of the cell-proliferation must be the chemical or physical action of endotoxins, enzymes or other substances produced as a result of metabolism and released at death.

"Furthermore," says he, "we must assume

[1] No doubt they were rod-shaped mitochondria (chondriconts), bacteria-like bodies looked upon as organs of elaboration, yet not formed out of the cytoplasm, but invariably derived from pre-existing mitochondria by division.

either that *Bacterium tumefaciens* is frequently accompanied by, or even supplanted by, another organism indistinguishable from it on agar-poured-plates and on other media, or else that some of its own elements within the tumour have lost all pathogenic power, as shown by our inoculations, while retaining the power to grow with the proper appearance on media."

This apparent occasional loss of pathogenic power strongly suggests some associated organism, not, however, indistinguishable from it, as conjectured by Dr. Smith, but very different and probably extremely minute. Besides, the failure to find *Bacterium tumefaciens* in hypertrophied or hyperplastic tissues surrounding crown-gall overgrowths and its absence from metastases and transplants of mouse and rat tumours obtained through the inoculation of strains of *Bacterium tumefaciens* isolated from human malignant neoplasms, render the acceptance of this organism as the true cause of cancer inadmissible. Yet, *Bacterium tumefaciens* seems to play a very important part in the incidence of crown-gall by favouring in some way or other the as yet unknown specific germ.

"Invisum Pecus," The Infinitely Minute.

In Strasbourg, the year before last, Professor Borrel showed me a flea the body of which was covered by tiny mites. The flea was a female specimen of *Ceratophyllus fasciatus*, obtained from the back of a laboratory mouse undergoing the tarring process. The mites were specimens of a *Tyroglyphus* in the curious *Hypopus* stage, during which, without functional mouth parts, but heavily cui-

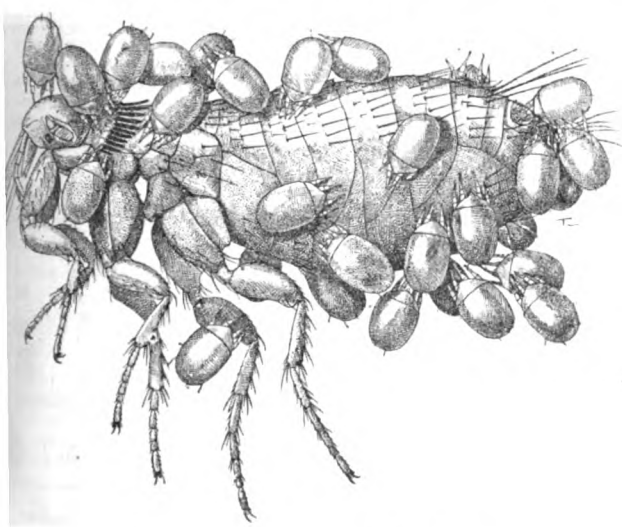

Fig. 53.—Rat flea covered with mites.

rassed and provided with ventral suckers, they attach themselves to beetles, flies, bees or other insects, merely to be transported, bur-like, from one place to another, just as occasionally do the head-louse and the book-scorpion (*Chelifer cancroides*), described by Aristotle as a tiny tailless scorpion.

The great Dutch naturalist and microscopist, Anton van Leeuwenhoek, was the first to observe the cheese or flour-mite riding upon fleas, and it was his observation which suggested the well-known lines of Swift—

> "Hobbes clearly proves that every creature
> Lives in a state of war by nature;
> So naturalists observe a flea
> Has smaller fleas that on him prey,
> And these have smaller still to bite 'em,
> And so proceed ad infinitum."

Even organisms consisting of one single cell are parasitised by smaller living things. Thus various Ciliates, such as *Paramecium*, *Stentor* and *Stylonichia*, often become the hosts of *Sphærophrya*, an endoparasitic Suctorian.

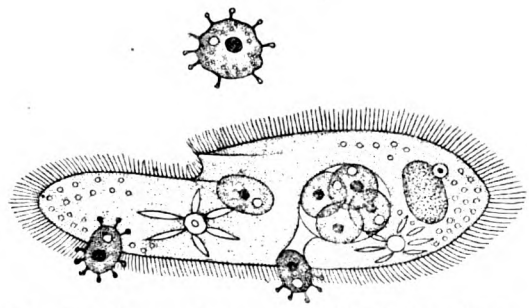

Fig. 54.—*Paramecium* parasitized by *Sphærophyra.*

Amœba proteus, the most familiar of Protozoa, and other unicellular fresh-water organisms are attacked by a smaller one-celled animal called *Nucleophaga*, because it penetrates the host's nucleus and grows and sporulates within. The infested nucleus becomes greatly hypertrophied with the growth of the parasite and, finally, the spores escape through rupture of the nuclear membrane.

Like Protozoa, so also bacteria have their parasites, messmates and symbionts and, no doubt,

Fig. 55.—Ross's "black spores."

D'Hérelle's "bactériophage" is a true parasite of Shiga's *Bacterium dysenteriæ*. It is a filter passer, as yet invisible, but fully demonstrable since it can be isolated, cultivated, and transmitted just like other parasitic microbes.

In 1900, whilst carrying out experiments and researches in the Roman Campagna, on behalf of the Colonial Office and the London School of Tropical Medicine, in order to provide irrefutable proof of the truth of the mosquito-malaria theory, I came across the "black spores" or "brown-bodies" believed by Ross to be

a kind of " enduring stage " of the malaria parasite. I found them not only in the oöcysts of *Plasmodium vivax* undergoing sporogony in the stomach wall of *Anopheles maculipennis*, but also on larvæ of *Dirofilaria immitis* developing within the Malpighian tubes of mosquitoes of the same species, and I discovered that, far from being a quiescent stage of the *Plasmodium*, or any part of its developmental cycle, Ross' " brown bodies " were its deadliest foes. They were hyperparasites of Anopheles, i.e., parasites of the " Cruel Filaria " and of the malaria parasite, both of which make use of *Anopheles maculipennis* as a necessary alternative host in their cyclical development.

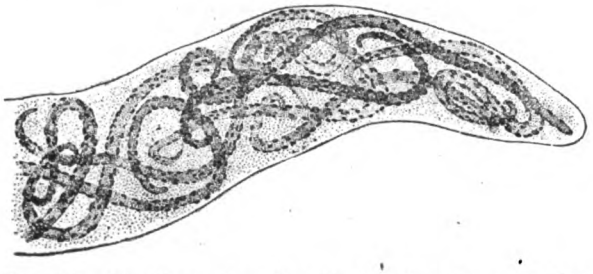

FIG. 56.—*Dirofilaria immitis* attacked by microsporidian within Malpighian tubes of *Anopheles maculipennis*.

A well-known instance of hyperparasitism is that of the Ichneumon flies. The parasitic larvæ of these Hymenoptera exercise a constant check upon the increase of moth and butterfly larvæ, of plant-lice (*Aphidæ*) and other insects injurious to plants, but they are themselves kept within bounds by hyperparasites, often of the same family, which detect at once a " stung " aphide or caterpillar and deposit their eggs in the body of the internal parasite. The larvæ hatched out of these eggs may also be attacked by smaller parasites, whose offspring in turn may suffer in like manner, the parasite being, possibly, some unicellular organism such as *Nosema ichneumonis*. It is a wonderful process carried on indefinitely far beyond our powers of investigation, and of which those " nested " Chinese boxes, which are enclosed one within another, are an apt illustration.

A knowledge of hyperparasitism has proved invaluable to agriculturists, and no doubt, in the future, it will prove of equal value to the sanitarian. Indeed, in the age of the great Oriental and Mediterranean civilizations, it was by pitting natural enemies against the fosterers and disseminators of disease germs that man conquered some of the more formidable of disease scourges, such as plague, malaria, hook-worm disease and endemic hæmaturia.

Vaccination still performed as in the days of Susruta; setons and issues still used as in the days of Galen, in ignorance, however, of their object: the pitting of pyogenic cocci against the plague bacterium; girdle, necklace, amulets and encolpia still worn, though no longer bearing insecticides against typhus-louse and plague-flea; consecration of cat, ichneumon, kestrel and rat-snake, nay, even deadly cobra, because destroyers of plague-carrying murines; domestication of snail-eating Ibis (*Ibis æthiopica*) against snail-fostered blood-fluke; protection of pellet-rolling dung-beetle (*Ateuchus sacer*) as a means of prevention against hook-worm disease; close-meshed cotton-net, gold-fish, duck, drain-pipe and smudge against plasmodium-bearing mosquitoes; loaf well raised with beer yeast; straw-covered wine-flask still holding an oil seal in its long, narrow gullet; Good Samaritan's oil-and-wine salve, testify not only to a knowledge of micro-organisms, but further to the judicious and salutary application of a knowledge which goes back to times prehistoric.

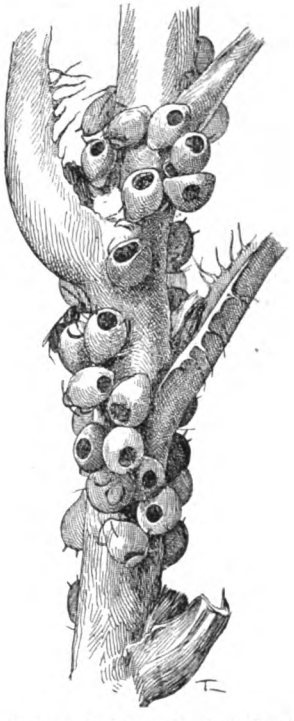

FIG. 57.—Dry, distended skins of plant-lice still clinging to black-currant stem and out of which have emerged *Ichneumonids* by cutting circular lids in the dorsal wall of their host's abdomen in the interior of which they have hatched, grown and pupated. (Original.)

Although the belief in micro-organisms as factors in the causation of fermentation and disease belongs to a very remote past, there can be no doubt that bacteriology is a comparatively new science. It sprang out of the remarkable observations of Leeuwenhoek, the true " Father of microscopy," who, with an instrument of his own construction (150 diameters against our 3,000), discovered, described and figured bacteria in 1683.[1]

I am glad that my medical studies began in the

[1] That lenses of different kinds were used in the remote past is obvious, when we consider that the Ancients were cognisant of many things which could not have been discovered without such aid.

Democritus (c 460-357 B.C.) knew the mountains and craters of the moon; to him the Galaxy, or milky river which foams athwart the sky, had resolved itself into countless stars. Aristotle (384-322 B.C.) knew the most minute structures of insects and mentions the skin-burrowing acarus (*Sarcoptes scabiei*) which, notwithstanding repeated rediscovery by Avenzoar, Redi, Wickmann and others, was unknown to the dermatologists of the XIXth century. Pliny, Ælian and Cicero describe the wonderfully minute carvings of Myrmecides, such as the ivory quadriga, with prancing horses and urging

very heyday of bacteriology, when discoveries of important pathogenic bacteria such as those of leprosy, typhoid fever, glanders, cholera, diphtheria, pneumonia, tetanus, tuberculosis and Wakker's hyacinth disease followed one another in rapid succession, because they impressed upon the mind the essentialness of a specific "contagium vivum" in all diseases.

The triumphs of bacteriology were closely followed by those of protozoology, especially in tropical pathology, Laveran leading the way with his discovery of the malaria parasite.

---

charioteer, that could find cover beneath the wing of a common house-fly.

Among the glyptic treasures of our museums are many examples of amazingly minute workmanship which could neither have been executed nor clearly seen and appreciated without magnifying glasses.

Moreover, have we not found ancient mirrors, plane, concave and convexed, made by Egyptians, Hebrews, Phœnicians, Greeks, Etruscans, Romans, Celts, Chinese, Mexicans and Peruvians? We have heard of burning glasses used from time immemorial, in both the old and the new world, to rekindle sacred fires. Several ancient authors, and among them Galen, state that at the siege of Syracuse (214-212 B.C.), Archimedes, the greatest mathematician and engineer of antiquity, burnt Roman galleys out at sea by the use of powerful mirrors. This seemed incredible, yet the famous Jesuit Athanasius Kircher, and, a century later, Georges-Louis Leclerc, Comte de Buffon, proved by actual experiment that it was possible.

The magnifying power of globular glass-vessels (*pila vitrea*), filled with water, was well known to the Ancients. Macrobius tells us how the inn-keepers of his day (5th century) used to display at the tavern door eggs, tripe, vegetables and fruit immersed in water contained in spherical glass vessels, in order that their comestibles might appear larger and more alluring. Seneca, explaining the formation of the rainbow in his "Questiones Naturales," says: "Every object much exceeds its natural size when seen through water. Letters, however small and indistinct, appear larger and more distinct when seen through a glass globe filled with water." Pliny, having mentioned the burning of cloth by means of a glass globe, adds: "Surgeons who have to cauterize certain parts of the body state that the most practical way is by using a crystal globe exposed to the sun's rays."

Well do I remember, as a child, seeing in Naples oranges, eggs, russet apples and sweet fennel in large water-filled glass globes at the show-windows of eating-houses, and cobblers working out in the streets at night with water-filled flasks on their benches to serve as light condensers in front of their wick-and-oil lamps.

It was by means of a small glass sphere placed against a hole in a thin metal plate, like a crystalline lens against its iris, that Robert Hooke, in 1663, examined the structure of a thin section of cork, discovered that plant tissues are made of a congeries of "little boxes or cells," and gave us the cell theory.

Simple microscopes, thus made from glass spherules or double convex lenses, are of very ancient design, no doubt suggested by the almost spherical or more or less flattened crystalline lenses found in the eyes of fishes, birds and mammals used as food. Indeed, all man's inventions have been judiciously borrowed from Nature. Porta's "Camera Obscura," now turned into our photographic camera, what else is it but the copy of the eye, a gigantic eye?

In the British Museum is an oval piece of rock-crystal, the size of a modern spectacle lens, cut and ground to a plano-convex form, which was found by Mr. Layard during the excavations of Sargon's Palace at Nimrud. This dates back to the seventh century B.C. and Sir David Brewster pronounced it to be a lens designed for the purpose of magnifying, but his authoritative opinion was discredited. However, other similar lenses were soon found at Pompeii, Herculaneum and Nola, and others again quite recently in Asia Minor. All of these are undoubtedly magnifying glasses.

Rock-crystal balls were made and used even for "scrying" long before our era. Many of these must have fallen and, breaking in the plane of cleavage, produced plano-convex lenses. Is it possible that the lapidary picking up the fragment, noticing its magnifying properties, never even thought of useful applications?

That Aristotle used a simple microscope, like that of Leeuwenhoek, is more than probable, but even combinations of lenses affixed to tubes may have been used. The lack of any actual description of such instruments in extant ancient literature is of little import. What shou'd we know of Etruscan dentistry had we not found in the ancient tombs of Corneto Tarquinia the very dentures with artificial teeth shaped from the lacteal incisors of cattle and held in position by perfect gold attachments—the very bridge-work of modern American dentistry? And what should we know of Greco-Roman catheters and trocars, of oral, rectal and vaginal specula, had we not found these instruments preserved beneath the volcanic dust blown out of the Vesuvian crater in its mighty explosive eruption of A.D. 79?

Truly we know nothing of the invention of either microscope or telescope. Authors, copying one another, usually ascribe the invention of the telescope to Hans Lippershey, or Lippersheim, in the year 1606 or 1608, stating, at the same time, that this man was not the inventor, since he borrowed the idea from Zacharias Jansen, adding, however, a tube. Jansen, we are told, was a Middelburg spectacle-maker. His children, while at play, happened to place two of his lenses, one behind the other, and were surprised to see the familiar weather-cock of the church opposite their house bow, grow larger and appear to approach them, with its lettered perch, when viewed through the combined glasses. Called to see the portent Jansen fixed the glasses on to an ornate board, and presented them, thus united, as a toy or "wonder" to "Prince" (Count) Maurice of Nassau who, being born in June, 1604, was either 2 or 4 years old at the time.

Govi ascribes the invention of the telescope to Galileo; others state that in 1609, having heard of Lippersheim's instrument, Galileo sat up all night and made a telescope out of an old organ pipe with a glass at each end (convex lens for objective and concave lens for eyepiece). A few years later, with an improved instrument, magnifying about thirty-three diameters, the great Italian physicist discovered Jupiter's satellites, the solar spots and the mountains and craters of the moon, but these discoveries were only rediscoveries, because, as already stated, lunar mountains, sun spots and Jovial satellites were known to the Ancients. The making of an astronomical telescope led Galileo to make a compound microscope, which likewise consists essentially of two lenses, an objective and an eyepiece, but both of short focal length. Girolamo Aleandro, writing from Rome in 1624, says that Galileo had invented an *occhiale* by means of which one could see a fly the size of a barnyard fowl. That Galileo made telescopes and microscopes there can be no doubt, but he never claimed the invention of either instrument.

Father Jean Mabillion, in his "Iter Germanicum," 1717, states that in a manscript of the thirteenth century he had found a miniature representing Ptolemy star-gazing through a very long tube. The early telescopes were all very long to insure high magnifying power and distinctness of image. Some of the telescopes of the middle of the seventeenth century were more than 200 feet in length.

Speaking of the "optic tube" as Milton called the Galilean telescope, the geographer Strabo (63 B.C.—A.D. 24) compares it to an older, more primitive telescope, possibly its prototype, the deep tubular well, in the water-mirror of which the stars can be seen at noon.

Pliny ("Nat. Hist.," Book 37, c. 15) relates that Nero watched the gladiatorial combats by means of an emerald and some authors have reasonably inferred from this statement that the emperor was short-sighted and that he corrected his myopia by making use of a concave cut emerald, but the majority of writers on the history of spectacles have repudiated this interpretation. They assume that eyeglasses were totally unknown before the thirteenth century and, therefore, conjecture that Nero merely amused himself at looking through a coloured gem, or mayhap, rested his sight thereby, because, as Pliny says: "Emeralds are the only gems which enrapture without satiating the eyes and will even soothe them when wearied by other sights. Gem engravers have no better salve for their

Now, however, like the ancients, we are ourselves surmising the existence of living organisms far smaller than any bacterium hitherto known. Ultra-microscopic organisms were first suspected in 1899, when Nocard found that the virus of cattle pleuro-pneumonia passed through bacterial filters. The number of recognized filterable viruses has grown considerably within recent years and includes the causal agents of several grave distempers. A disease of special interest to us is the common wart (*Verruca*), a filter-passer the mild contagiousness of which has been known for centuries.

At one time microbial activity was considered to be an enzymic chemical process, now we may have to look upon the enzyme as a living thing.

The analogy between enzymes and toxins is striking, and I venture to suggest that many zoo-toxins, such as snake venom, may be due to filter-passing viruses.

In the first place, it is well known that while certain snakes are harmless, others are deadly. The latter are provided with poison-glands, containing a lethal fluid, and with grooved or tubular fangs, wonderfully adapted to its inoculation. The venom-gland is a modified salivary gland, the tubular fang a modified tooth. These structural modifications, of which we find every gradation represented among the various snakes, show that venom-gland and poison-fang have gradually developed in response to some animate stimulus. Surely, it cannot be unreasonable to compare the remarkable, highly-specialized fang-mechanism of vipers and rattle-snakes with the innumerable and wondrous modifications which have taken place in the structure of flowers and insects, in adaptation to requirements necessary to ensure cross-pollination. And, certainly, we cannot overlook the striking resemblance between the grooved or tubular poison-fangs of snakes and the enlarged, hollowed and perforated thorns of species of *Acacia* tenanted by arboreal ants, which protect the host-plant against leaf-cutting myrmicines and other injurious insects.

Most suggestive is the fact that snake-venom is stored, but not necessarily elaborated, within the poison-gland. The blood of both harmless and

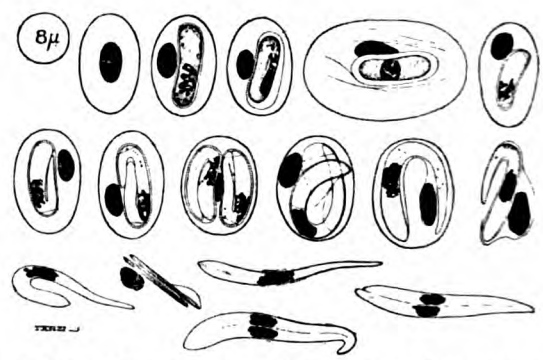

FIG. 57A.—*Hæmogregarina seligmanni* Sambon 1907, from Bushmaster (*Lachesis mutus*). Sporonts in normal-sized erythrocytes, schizonts in greatly enlarged erythrocytes. Free forms, conjugating forms and rolled up empty capsules.

venomous snakes is toxic and its toxicity is the same as that of the gland-venom, both giving rise to the same symptoms when subcutaneously or intravenously inoculated. Indeed, Calmette has shown that cobra blood-serum confers a more powerful immunity than cobra-venom. It seems, therefore, that the blood is the true habitat of the specific virus. Moreover, the same toxic agent is found in the yolk of snakes' eggs, suggesting transmission to the progeny of what appears to be a valuable symbiotic organism. Though deadly, if inoculated subcutaneously, the venom of the viper is harmless if swallowed, even in large doses, as Redi's famous experiments proved two and a half centuries ago. Another instructive fact is the seasonal variation in toxicity; the venom of *Vipera aspis*, whilst almost innocuous in the month of April, becomes powerfully toxic in May.

An example parallel to that of venomous animals is offered by luminous animals. Bioluminescence has been studied by the chemist with mortar and test-tube, and he has given us many "luminous" names, such as noctilucin, luciferin, luciferase, pre-luciferin, coluciferase, photogenin, photopelein

---

eyes, because with their verdant softness they allay fatigue, besides they make it possible to use the eyes for a longer period casting by reflection their colour to all around."

I do not think there can be any doubt that Nero used his emerald or beryl (since Pliny's term smaragdus comprises both) either as a single eyeglass or as a mirror. Pliny tells us that "most emeralds were concave," we may therefore reasonably assume that the one used by the Emperor was also concave and that he used it to correct the myopia of his dull grey eyes. However, it is also possible that the stone had a flat surface and was used as a mirror. Pliny remarks that, when the surface of the smaragdus is flat, it reflects the image of objects in the same manner as a mirror and, indeed, by holding the flat surface of an emerald close to the eye, distant objects can be distinctly seen reflected on it. The great Franciscan friar, Roger Bacon, mentions how a plano-convex lens held in the hand "is useful to old men and those who have weak eyes."

It is very probable that Nero watched the games, just as another famous myope, Pope Leo X, watched, through a concave glass, hawks and eagles high up in the air, or far away in the fields, swoop to their prey.

In connection with the use of emeralds as single eyeglasses, spectacles or mirrors in the first century, it is interesting to note that beryl, a variety of emerald, was the material chiefly used in the manufacture of spectacles when, twelve centuries later, we find them common and in general use. The great French surgeon, Guy de Chauliac, writing in 1363, says: "Should these collyria fail, it will be necessary to use spectacles either of glass or beryl." Beryl was so generally employed that in France the very name of eyeglasses was "bericles," "besicles," or some other corrupt form of the term beryl. Tortelli, in his work "De Orthographia," Venice, 1471, mentions that spectacle lenses were cut of glass, crystal, or beryl.

In China the use of spectacles appears to be very ancient, for spectacles of rock-crystal and beryl are reported by the earliest travellers. Imperial Rome held commercial intercourse with China, for Florus states that Augustus received a Chinese embassy and it is possible that Chinese eyeglasses were brought over at that time. Certainly they were introduced or reintroduced into Europe in the thirteenth century by missionaries and merchants who visited China about that time. Among the latter, Marco Polo stands out a prominent, well-known figure. In any case, it is certain that Italian monks were among the first spectacle makers and that Venice long held the monopoly.

oxyluciferin, and luciferescine, but little else. With Pierantoni (1918), I am inclined to believe that the luminescence of the photogenic organs of fire-flies and other lantern-bearing animals is due to the presence of luminous symbiotic organisms. During pupation the light organ of the larval fire-fly is transformed into the new lamp of the imago, and the latter will oviposit luminous eggs. The unicellular and multicellular photogenic-glands of luminous animals contain " luciferine granules " in every way comparable to the " zymogene granules " of digestive-glands and to the " venogene granules " of venom-glands, and, no doubt, to the granules or " coccoid bodies " which, as I have shown, occur in the endocellular stage of spirochætes.

The photogenic material from luminous-glands, the rennet or other ferment from digestive-glands, the venom from poison-glands and Rous' fowl sarcoma, may be desiccated, and all will, in this state, preserve their activity, a striking characteristic action active in infinitesimal dilutions.

In my first cancer report (June 2, 1924), I said: " If it be true that the most diverse forms of irritation, animate and inanimate, may give rise to cancer, then surely the cancer germ must be some frequent and ubiquitous micro-organism, like the germ or germs which, in association with *Filaria bancrofti*, or some like factor, bring about those enormous tumour-like formations we call elephantiasis and pachydermia.

" Failure hitherto to find the cancer germ may have been due to faulty technique or to extreme minuteness. Recently, indeed, Rous and his fellow-workers have found that chicken tumours of connective tissue type may be reproduced in healthy fowls of the same breed by the injection of cell-free extracts of these tumours. In each case the neoplasm produced in the inoculated fowl resembled the tumour from which the extract was made. This shows that the type of tumour is determined by the individuality of the causative agent and not alone by the potentialities of the stimulated cells. The work of Rous and others seems to show that particular neoplasms have specific causative agents which in some cases can be separated from the neoplasm. They appear to be living ultramicroscopic organisms able to pass through a Berkefeld filter impermeable to *Bacillus fluorescens liquifaciens*. Already several diseases have been shown to be due to so-called filtrable viruses."

In my second report (February, 1925), I said: " Whatever be the rôle of parasitic worms, the actual essential cause of cancer is some ubiquitous micro-organism, probably a filter-passer, as the researches of Rous and his fellow-workers seem to indicate, but this parasite, apparently, is unable to thrive except in tissues of low or lowered resistance. We see it therefore affect embryonic residues, pigmentary moles, burn scars, goitrous thyroids, breast adenomas, the margin of gastric ulcers, the lesions of dysentery, syphilis and tuberculosis, as well as those caused by the irritation of foreign bodies or by the parasitism of helminths."

These views were soon supported by Dr. W. E. Gye's " Researches on the Ætiology of Malignant Growths," published in the *Lancet* of July 18, 1925. Gye has not only confirmed Rous's findings, but duplicated them with mouse, rat and human malignant neoplasms which, hitherto, had not been propagated by cell filtrates. Gye's work inspires confidence; it shows consummate technical skill, great acumen and sound judgment. Gye has succeeded in isolating, incubating, and breeding a specific ultramicroscopic endocellular organism which, in nature, requires peculiar conditions of tissue irritation that it may cause overgrowths. In his experimental work (by inoculating, together with the " virus," the necessary cell-irritant extracted from tissues already cancerous) he has overcome this difficulty so successfully that he has obtained 100 per cent. of " takes." Gye has shown that the virus is not so strictly specific as formerly believed since it can be supplied by tumours of other kinds and from widely different species of animals. This, however, had already become evident when the Japanese Shirai proved that rat sarcoma could be grafted successfully upon the brain of rabbit, mouse and pigeon. The main difficulty lies not with the parasite, but with the host, and, no wonder, since the cancer germ is an endocellular organism, just like the malaria parasite and an infinity of other endocellular parasites (*Hæmogregarines*, *Leucocytozoa*, *Spirochætes*, &c.) of strict specificness, because of their restriction to particular cells such as erythrocytes, leucocytes, or vascular endothelial cells. An appropriate and cogent example is that of *Rickettsia* in typhus fever. The parasite affects almost exclusively the endothelial cells of the capillaries. The reaction to the parasite is shown by proliferation on the part of the endothelium, giving rise to characteristic intravascular nodules (" nodules " of Fraenkel) in skin and central nervous system. The virus (*Rickettsia prowazeki*) is present in the cells of the proliferative lesions and is carried into the nerve tissue by the migration of infected endothelial cells.

Remedies Old and New.

With regard to treatment, I have nothing of importance to report. Dr. C. Bakker, of Broek, North Holland, who is a keen student of folk-lore, told me that in the Netherlands the greater celandine (*Chelidonium majus*) was long considered a specific against cancer.

In Villa Lagarina, whilst inspecting the garden of one of the houses of Via Damiano Chiesa in which no less than five cancer cases had occurred, I came across a large cluster of the celandine, unmistakable in the glaucous colour of its beautiful pinnately-lobed leaves, in the bright gold of its flowers, large as buttercups. I broke some of the delicate branches to see the " Devil's milk "—its saffron-coloured latex—ooze out, and a distinguished engineer, Signor Sandona, who was showing me round, told me that in Italy also this plant is looked upon by rustics as a valuable remedy in the treatment of oral and cutaneous cancer. Certainly, with us, its

orange, acrid, caustic juice has long been used to destroy warts, as some of the plant's popular names —kill-wart, wart-weed, wart-wort, felon-wort and wart-flower—clearly indicate.

Chelidonium majus is a perennial, deciduous and herbaceous plant belonging to the poppy family; it is widely distributed throughout Eurasia, but the proximity of its stations to villages, farmhouses, ruins and cottage-hedgerows points to its use by man during long ages.

By the rule of signatures it was supposed to be intended as a remedy for the jaundice, its yellow latex corresponding with the yellow hue of the patient. For this purpose its leaves and stalks were boiled up with strawberry leaves. When given internally, in large doses, it excites violent purging. Externally the fresh latex acts as a local irritant and was used not only to destroy warts on hands and face, but also, mixed with woman's milk, to remove pannus and opacities from the cornea. Already Pliny the elder speaking of celandine or swallow-wart says: "It is by the aid of this plant that the swallow restores the sight of its fledglings in the nest, even though their eyes be plucked out!" This belief was held by Dioscorides and other earlier Greek authors, hence the ancient name of the plant derived from the Greek word chelidon, a swallow. Mixed with sulphur it was used in the treatment of scabies.

The greater celandine contains several alkaloids such as chelidonine (identical with stylophorine), chelerythrine (which is fluorescent) and protopine combined with organic acids such as chelidonic, malic, citric and tartaric. It also contains chelidoxanthin, a bitter neutral principle, possessing a yellow colour and resembling berberine.

Dr. Bonne told me that some weeks before our trip to Zeeland a local quack had been fined and imprisoned for having split open a live puppy-dog and applied it to a cancer of the breast.

The application of dogs, cats, fowls and pigeons to a diseased part of the body, split open, warm, palpitating, was a common practice throughout the middle-ages in the treatment of the most diverse diseases such as colic, pleurisy, megrim, abscess, rheumatism, gout and epilepsy. Dr. Coulon, in his "Curiosités de l'Histoire des Remèdes," 1892, quotes from a medical and pharmaceutical dictionary of the eighteenth century the following prescriptions:—

"A cat cleaved lengthwise, after decapitation, and applied whilst still warm, relieves intercostal pain.

"A black barn-fowl, split open alive and immeditely applied to the head may be of use against headache and frenzy.

"A pigeon split open and applied whilst warm and living to the shaven scalp will sooth melancholia and dissipate sadness."

Quite recently, Professor Fichera has advocated the application of fresh splenic pulp to open cancers.

In the course of my recent peregrinations, I met a physician who said the best remedy, the best preventive would be the early enforcement of euthanasia in all cases. I told him his method of treatment was no novelty. Already long ago, the Russians had, trained cannon on plague-stricken villages, forgetting the part played by rats and fleas in the dissemination of the disease. Theodore, the mad King of Abyssinia, had invited the lepers of his kingdom to a great banquet and, when strong mead had made them somnolent, he had fired the banqueting hall. Gui Patin (February 1, 1657) gives definite instructions for the treatment of patients suffering from rabies; he says: "They must be smothered in their beds with quilts and blankets, or forced to swallow a pill containing six grains of pure opium in order that nothing more need be said about them." To-day foot-and-mouth disease in cattle is being treated by wholesale slaughtering! God forbid that, in our ignorance, we should extend such methods!

Summary.

Facts Observed, Experiments Made, and Conclusions Reached.

During the last three years, whenever possible, I directed my attention and activities to the study of the natural history of cancer in different countries. In this work I was assisted by distinguished physicians and naturalists, well-known experts in their own branches of research. Thus already many facts have been examined and observations and experiments made which bring valid support to the parasitic theory of cancer and point to some microscopic or ultra-microscopic organism as the *causa causans*.

Epidemiological Investigations.

Whilst much important work has been and is being carried out by numerous investigators in hospital and laboratory, I decided to endeavour to elucidate the ætiology of cancer by a careful investigation of its endemiological and epidemiological features, studied directly in the field.

My investigations, commenced in tropical (West Indies) and arctic (Iceland) regions, have been continued, during 1925, in some of the lowlands (Holland) and mountainous districts (Eastern Alps) of the temperate zone, in country and town, among vegetarians and meat-eaters, in man, animals and plants, that the survey might be comprehensive.

The results of the recent endemiological investigations (1925) confirm and extend those previously made; they are definite and fully documented (the case-lists and distribution maps are signed and stamped by local physicians and by civil and ecclesiastical authorities); they certainly dispose of a number of groundless theories which only impeded further scientific research.

It has been ascertained that:—

(1) Cancer distribution and prevalence vary from place to place, often considerably, irrespective of climate, race, food, type of dwelling, habits and customs.

(2) The organs, or parts of the body, more frequently affected by cancer vary, not only in countries far removed from one another, but also, and often strikingly, in adjoining districts.

(3) As a rule, cancer cases are distributed in groups or clusters. A first case is usually followed by one, two, three, or more cases, either in the same house, or in adjoining, or neighbouring houses, the successive patients being sometimes related, more often not.

(4) Frequently, in a cancer cluster, all, or the majority of the patients, whether related or not, are affected in the same organ, or in the same part of the body, indicating, very probably, a common source of infection.

(5) Notwithstanding occasional increase in certain localities, decline in others, the relative frequence of regional incidence shows that same remarkable persistence which is characteristic of the "stations" of well-known endemic diseases.

(6) Notwithstanding general progressive increase or decline, cancer exhibits, in its local incidence, noticeable fluctuations from year to year, such as are witnessed in all endemic diseases.

(7) For a number of years cancer may prevail exclusively in one section of a region, town, or village, then affect some other section, whilst continuing, increasing, diminishing, or maybe even dying out in the section previously affected.

(8) Cancer may break out suddenly in a place long immune, then disappear, or it may remain quiescent, at least in so far as man is concerned, for many years.

(9) Heredity is not a determining factor. While in certain villages many family cases were investigated, in others no blood relationship whatever could be traced between any of the numerous cases which had occurred during periods of from forty to fifty years. Moreover, it was found that cancer might appear first in the children, and later, sometimes much later, in the parents, or almost simultaneously in both.

(10) The habitation of certain premises appears to be a factor of importance, at least whilst as yet undetermined cancerous conditions persist.

The term "cancer-house" may be a misnomer, but, none the less, it is certain that certain houses because of the repeated occurrence of the disease in different families inhabiting them successively, have gained an evil reputation and the popular name of "cancer houses." Irrefutable examples are mentioned. Cancer in husband and wife is frequently observed. Often a primary case is followed by malignant disease in members of the same household, not always in a blood-relative or spouse, but often in brother-in-law or sister-in-law, step-son or step-daughter, maidservant or lodger.

(11) Under the same roof, cancer in dog, cat, fowl, or other domestic animal occasionally may be found in association with cancer in man, either preceding or following it.

The Harlingen and Birmingham cases quoted seem deserving of consideration.

Parasitological Researches.

Our field investigations having shown that cancer is a place-, often a house-disease, a study of the flora and fauna of cancer-houses (houses with more than two non-related cases) and their surroundings was indicated. In the course of this work, by no means completed, several lines of investigation were and are being followed.

The Report deals with the consideration of certain helminths of animals (some occurring also in man) as possible mediate agents in the incidence of cancer. By their destructive activities these parasites often incite cell-proliferation and the lesions produced, or the reparative hyperplasia which follows, seem to be favourable factors in the development of cancer.

During recent investigations in Holland and Italy many household pests were collected, as well as parasites found in and upon domestic animals and house vermin. Of the collected material only such part as was considered to be relevant received special attention.

Among the helminths discussed are certain species or races of *Gongylonema* (*G. pulchrum*, *G. scutatum*, *G. neoplasticum*, &c.) from pigs, cattle, sheep, goats, rats and mice; *Trichosomoides crassicauda*, *Muspicea borreli*, *Heterakis isolonche*, a new species of *Hepaticola* and *Hydatigera tæniæformis*.

Incidentally, experiments were made with the cattle *Gongylonema*, its local intermediate hosts (several species of dung-beetles), and the two kinds of cockroaches (*Blatta orientalis* and *Blattella germanica*) found in the Trentino.

(1) Household insects, such as *Blatta*, *Blattella*, *Blaps*, *Tenebrio* and *Ephestia*, were not found to be infected with *Gongylonema* in Northern Italy.

(2) Four species of dung-beetles (*Onthophagus taurus*, *Caccobius schreberi*, *Aphodius hæmorrhoidalis* and *Oniticellus fulvus*) were found, in the same region, to be naturally infested with larvæ of *Gongylonema*, presumably of the cattle form (*G. scutatum*). No other natural intermediate hosts for *Gongylonema* were discovered.

(3) The German cockroach (*Blattella germanica*) was successfully infested by feeding it with the eggs of the cattle *Gongylonema* (*G. scutatum*), but several attempts to infect the larger, more common Oriental cockroach (*Blatta orientalis*) failed, though this species, like *Blattella germanica*, is known to foster the larva of the rat *Gongylonema* (*G. neoplasticum*).

(4) Rats fed on cockroaches collected in the houses of Villa Lagarina and other Trentino villages did not become infected with *Gongylonema*, a fact which confirms the negative results obtained through the laborious dissection of these cockroaches.

(5) Two sheep, two pigs and a calf of British breed were fed in London with naturally infested dung-beetles collected by Dr. Scrinzi in the neighbourhood of Villa Lagarina. The larvæ fostered by these beetles were those of the cattle form of *Gongylonema* (*G. scutatum*). Calf and sheep became heavily infested, while the pigs remained immune.

A case of *Gongylonema* infestation in the human being—a young woman of Saracinesco (Tivoli)—

reported by Professor Alessandrini of Rome in 1914, was traced, the patient and the extracted nematodes examined, the locality of infestation visited and evidence obtained which shows that the parasites extracted from the girl's mouth do not belong to a new species, as suggested by Professor Alessandrini, but are, very probably, specimens of the hog Gongylonema (*Gongylonema pulchrum*).

Of about ninety rats captured in or near Villa Lagarina (chiefly young ones) two had mammary tumours and one was affected by two neoplasms of different type: a benign fibro-adenoma of the mamma and a malignant gastric tumour. The cancerous neoplasm arose as a papillomatous growth from the cardiac portion of the stomach, which harboured specimens of *Hepaticola gastrica*, a new *species* of Trichurid worm hitherto confounded with *Hepaticola hepatica*, and described by Dr. Baylis. One, possibly two, of these nematodes and some of the extruded characteristic ova were embedded in the neoplasm.

Part Played by Helminths in the Ætiology of Cancer.

A significant example of the mediate agency played by Helminths in the production of cancer is the presence, in rats, of malignant neoplasms of different type in different organs, each associated with the helminth peculiar to that particular organ and varying in incidence in different regions with the distribution and prevalence of each helminth.

The following instances may now be cited:—

(*a*) Liver sarcoma associated with the *Strobilocercus*, or strobilate form of *Hydatigera tæniæformis* which encysts in the rat's liver (Borrel, Bridré, Bullock, Curtis, Conseil, McCoy, Regaud, Wherry, and others).

(*b*) Gastric carcinoma associated with *Gongylonema neoplasticum*, which excavates galleries in the pavimentous epithelium lining the cardiac portion of the rat's stomach (Fibiger, Wassink).

(*c*) Gastric carcinoma associated with a new species of *Hepaticola* (*H. gastrica*), which also excavates galleries in the pavimentous epithelium lining the cardiac portion of the rat's stomach (Baylis, Beatti, Bonne, Sambon, Wassink).

(*d*) Cancer of the bladder associated with *Trichosomoides crassicauda*, which in its adult stage dwells in the rat's urinary bladder (Löwenstein, Sambon, Saul, Thomas, Wassink).

The reality of this agency is confirmed by the experimental production, on a large scale, of malignant growths in the rat through the administration of the eggs of *Hydatigera tæniæformis*, or of the larvæ of *Gongylonema neoplasticum*. These experiments, many times repeated by different investigators, prove that by irritation and consequent hyperplasia, any of the various helminths mentioned, and probably others, may incite, or favour, the production of neoplasms, provided the necessary causative factor be also present, either brought in by these helminths, in their early migrations, or otherwise introduced.

In man, the presence of certain helminths, acting as living irritants in the particular organs they invariably affect, explains most satisfactorily some of the more striking differences in the body location of cancer noticed in different districts and countries inhabited by such helminths. Instructive examples are:—

(*a*) *Schistosoma hæmatobium*, associated with carcinoma of the urogenital system in Lower Egypt.

(*b*) *Schistosoma mansoni*, associated with carcinoma of the large bowel and perineum in Lower Egypt.

(*c*) *Schistosoma japonicum*, associated with hepatic cancer in the Island of Kyushu (Japan) and other low-lying parts of China and Japan.

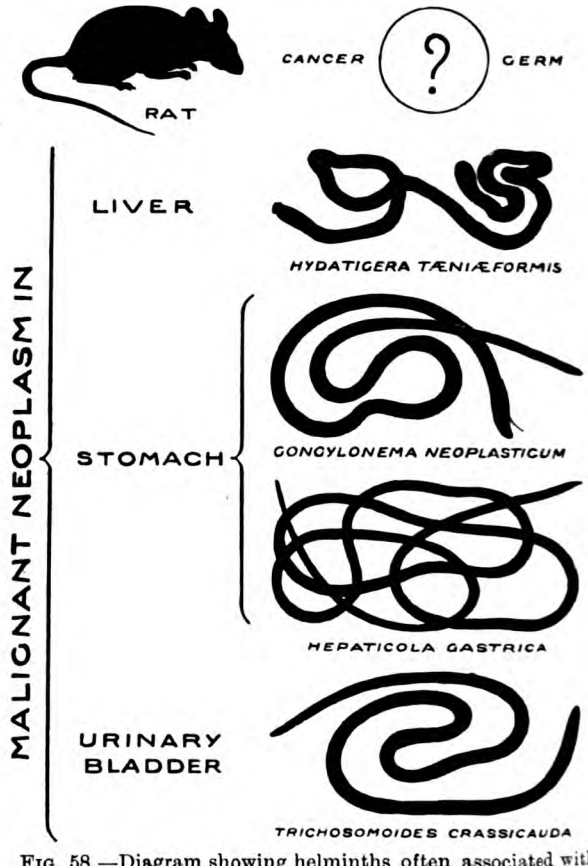

Fig. 58.—Diagram showing helminths often associated with cancer in the rat and apparently determining its visceral location.

(*d*) *Opisthorchis felineus*, associated with primary cancer of the liver on the mainland shores of the Kurisches Haff (East Prussia), in eaters of raw fish.

(*e*) *Trichinella spiralis*, *Oxyuris vermicularis*, *Clonorchis sinensis*, and other helminths associated with neoplasms in the organs they respectively affect. The agency of these latter worms, however, has not yet been substantiated definitely.

The mediate agency of various helminths in the production of cancer in man, within the organs of the body which they respectively affect, is supported by the similar, yet different, visceral distribution of

malignant growths in domestic and wild animals. The difference is in the site-incidence, which varies in the different zoological species with the variously located helminths peculiar to each species, as has been shown in the case of the rat and other animals. A singularly striking example is the occurrence of epithelioma of the lachrymal caruncle in cattle, probably incited by *Thelazia rhodesi*, a Spirurid worm which affects the excretory ducts of the lachrymal glands.

Moreover, the agency of animate irritants is paralleled by that of inanimate irritants (physical, chemical, mechanical), so universally admitted and by many considered to be the all-sufficient cause of cancer.

Recognition of the frequent, indubitable association of neoplasms with helminths or other parasites (acari, protozoa, bacteria) assumes paramount importance, when we realize that it indicates very definitely a possibility of controlling the disease in so far as it is brought about by the mediation of certain parasites, because, as is well known, the elimination of parasites and their carriers lies well within the scope and power of preventive medicine.

Plant Cancer.

In view of recent findings (Smith, Blumenthal, and others), the distribution of crown-gall (plant-cancer) was studied in its possible relationship to cancer distribution and prevalence in the Trentino, where it is well known to agriculturists, pomologists and wine-growers, who call it "gozzo" (goitre), "rogna" (scab), and "marezzo" (crispation), and occupies a range co-extensive with that of cancer. *Bacterium tumefaciens* does not seem to be the true cause of plant cancer, but it probably is of importance as an auxiliary factor.

Should the "virus" of human and animal cancer prove to be the same as that of plant cancer, as Blumenthal's experiments seem to indicate, its ubiquity would be easily understood, since crown-gall is common in the tobacco-plant, in the majority of food-plants (such as potato, cabbage, tomato, carrot, turnip, sugar-beet, radish, lettuce, apple, pear, plum, peach, cherry, raspberry, blackberry, grape, walnut, chestnut, &c.), and in many of the ornamental plants (such as rose, carnation, geranium, chrysanthemum, honeysuckle, sunflower, oleander, poplar, willow, &c.), usually introduced into our gardens and houses.

The "Virus."

The nature of the cancer "virus" is discussed. The views expressed in the two previous reports are upheld and the findings of Peyton Rous, recently confirmed and extended by Gye, are regarded as most important.

Finally, zymogen, venogen, and luciferine granules are looked upon as symbiotic organisms, the further study of which is likely to throw light on the cancer germ and other "filtrable viruses." They are comparable to the granules or "coccoid bodies" of spirochætes which may be seen in the blood-cells of their vertebrate hosts and in the body-cavity, salivary glands, ovaries, and eggs of their invertebrate hosts.

We are on the threshold of a vast world of minimal forms of life even more wonderfully and fearfully made than those which antiquity surmised and the eighteenth century revealed.

CANCER OF THE STOMACH OF THE WILD RAT AND INFECTION WITH A NEMATODE WORM, *HEPATICOLA GASTRICA* BAYLIS, 1925.

By C. Bonne.

In 1925 Dr. L. W. Sambon invited me to join the Cancer Field Commission of the Tropical Diseases Prevention Association on a visit to the province of Trentino in Italy. This commission, which was engaged in an epidemiological study of cancer in certain villages in the said province had its headquarters at Trento. Rats were collected in the village of Villa Lagarina, and in August, 1925, I had the opportunity of examining one of these, a freshly-killed, full-grown brown rat (*Rattus norvegicus*), body length 22 cm., with a tumour-like growth in the right mammary region, between the second and the third thoracic nipples. The skin was bulging out at this place and had lost part of its hairs. After opening the rat there appeared to be present under the skin a tumour of the size and shape of a small chestnut (fig. 27), not very hard of consistence, and rather freely movable with regard to skin and thoracic wall. The surface of the well-defined tumour was rather smooth, but a definite fibrous capsule was not recognizable. In the stomach there was a second tumour, about the size of a cherry stone or a little larger. It was a papillomatous growth in the cardiac portion of the stomach, protruding into the lumen of the organ (fig. 28). The glandular part of the stomach looked normal. In the pavimentous epithelium of the cardiac portion of the stomach, a few nematodes were lying in sinuous galleries, which were identified by Dr. Baylis, helminthologist of the British Museum, and member of the Cancer Field Commission, as *Hepaticola gastrica* (fig. 42). One of these nematodes was seen in the immediate neighbourhood of the tumour. No tumour metastases were seen in lymph glands, liver, lungs or elsewhere.

In returning to the Leeuwenhoekhuis in Amsterdam, I took with me the stomach of the rat and part of the breast tumour. Histologically the type of breast tumour was not very readily comparable to the ordinary types of human breast tumours (fig. 60). In the well-developed stroma we see groups of tubules, usually lined with a single layer of epithelial cells. The tubules are arranged in lobules as we see it in the normal mammary gland. In many of these lobules, however, there is a reduction of the epithelial part and an excess of connective tissue resembling pericanalicular fibroma in man. In other lobules there is a proliferation of the epithelial part. No definite degenerative changes or definite signs of inflammation are visible. The tumour could be classified as a fibro-adenoma of benign character. Serial celloidin sections were made of the stomach tumour and of the adjacent part of the stomach wall.

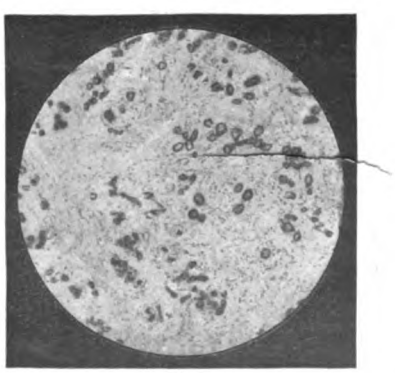

Fig. 60.—Section of rat's mammary tumour.

The sections show an enormous papillomatous growth involving the epithelium, the muscularis mucosæ and the submucosa. The muscle of the stomach wall passes beneath the tumour unmodified (fig. 61). The stem of the papilloma is very broad; wide blood-vessels are present in it. In following up the serial sections it soon becomes obvious that the tumour does not present the same character in all its parts. At a certain point the epithelium begins to grow downward into the broad stem of the papilloma, it invades the muscularis mucosæ, penetrates through it, destroys it completely and spreads in every direction, until it reaches the muscular layer. The surrounding connective tissue shows an intense infiltration with round-cells and leucocytes with a certain degree of eosinophilia. The growth of the tumour-cells in the deeper part of the stomach wall is very atypical. There is not only a definite polymorphia, but this invading part of the tumour in certain areas also entirely loses its character of stratified pavimentous epithelium. From a histological point of view this change in character is extremely interesting. The cells at the periphery of the cords show a palisade arrangement as in basal-cell carcinoma (fig. 62). The centre of the tumour cords shows necrosis or shows an opening, and very often the layer of cells bordering this central lumen shows palisade arrangement in the same way as the cells at the periphery (fig. 63). As

Fig. 61.—Section of stomach tumour (low power).

a result of this process, certain parts of the tumour simulate adenocarcinoma. This resembles very much what is found in many tumours in the human

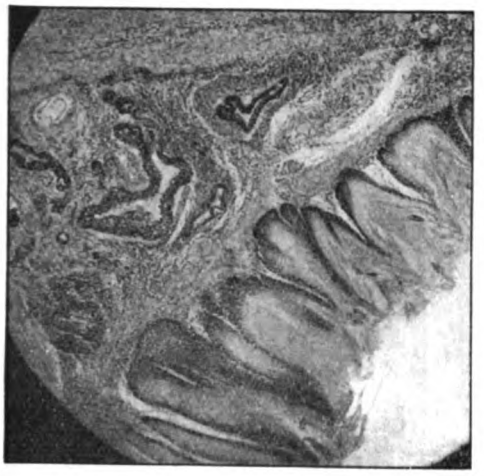

FIG. 62.—Growth of tumour beneath slightly hypertrophied epithelium of stomach.

FIG. 63.—Palisade arrangement of cells lining central lumen of tumour cords.

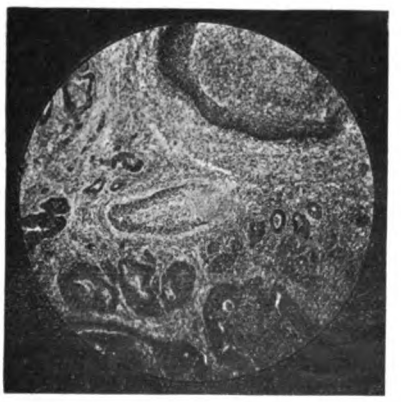

FIG. 64.—Blood-vessel showing partial thrombosis and filled with tumour cells (serial section 178.)

body, sometimes of uncertain origin. In tumours around the nasal cavity, e.g., a similar histological picture is often seen. The rat tumour shows quite clearly that this type of neoplasm may arise from the ordinary stratified pavimentous epithelium. The invading atypical growth classifies the tumour as an epithelioma, a cancer, and any hesitation about it is removed by the fact that an indubitable invasion of blood-vessels is visible in a large series of sections (figs. 64, 65).

FIG. 65.—Same vessel as fig. 64. Elastine staining (serial section 183).

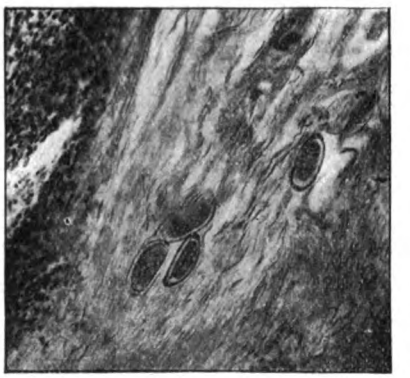

FIG. 66.—Eggs of *Hepaticola gastrica* in epithelium.

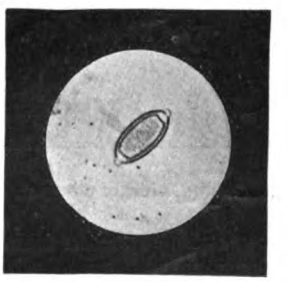

FIG. 67.—Egg of *Hepaticola gastrica* from rat's stomach.

Is the presence of the tumour and of the *Hepaticola* merely a coincidence, or is there a causal connection between the two?

Through Fibiger's work we knew already that spontaneous tumours of the stomach of the rat of a certain size were extremely rare. He found no true new growth in 1,144 rats examined. Wassink examined the stomachs of 625 rats from various

sources in Amsterdam and 625 other rats from ships, and never found a definite spontaneous tumour in the stomach. Fibiger, as well as Wassink, found stomachs, infected with *Hepaticola*, many times, but never with definite tumour formation. Wassink has kindly shown me his slides of *Hepaticola*-infected rat stomachs, which did show some epithelial reaction. In his most pronounced case there was

FIG. 68.—Eggs of *Hepaticola gastrica* in epithelium (cross section).

a formation of relatively large epithelial cysts filled with horny masses. For these reasons Fibiger and Wassink concluded that *Hepaticola*, or *Trichosoma*, as it was called by them, could not cause tumour formation; it seemed as if *Gongylonema neoplasticum* was the only worm capable of producing cancer in the stomach of the rat.

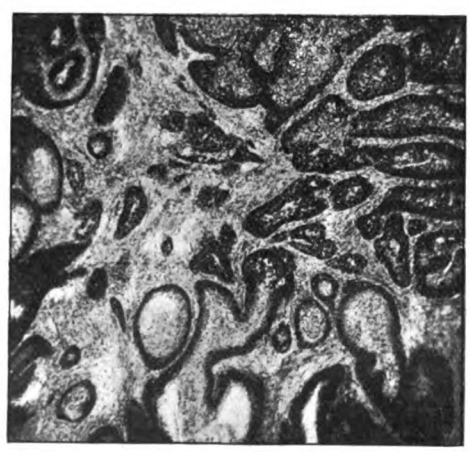

FIG. 69.—General view of stomach tumour.

Beatti, however,[1] has reported from Buenos Aires the finding of three rats infected with a nematode which he identified as probably *Hepaticola hepatica*, and presenting a tumour of the cardiac portion of the stomach. Two of these tumours are described as papilloma, sarcoma and epithelioma, all present at the same time in one stomach; the third tumour is described as an epithelioma. This last case and one of the other cases had metastases in lymph glands and liver. In the rat from Villa Lagarina, described here, there was no trace of sarcoma. From the description of the worms and their eggs, there seems to be little doubt at present that Beatti had really *Hepaticola gastrica* before him. In all four cases, the presence of *Gongylonema*, together with *Hepaticola*, in the same rat must be excluded, especially in South America, where *Gongylonema neoplasticum* is known to occur.

FIG. 70.—Cross section of *Hepaticola gastrica* in stomach tumour.

Fibiger received it from the West Indies, Wassink received it from Surinam, and recently I received them myself again from Surinam. But, of course, from the West Indies to the Argentine is a long distance and I do not know of any report of *Gongylonema neoplasticum* from the Argentine. Also from Italy *Gongylonema neoplasticum*, as far as I know, has never been reported, and I have not been able to find it in the Villa Lagarina rat, which

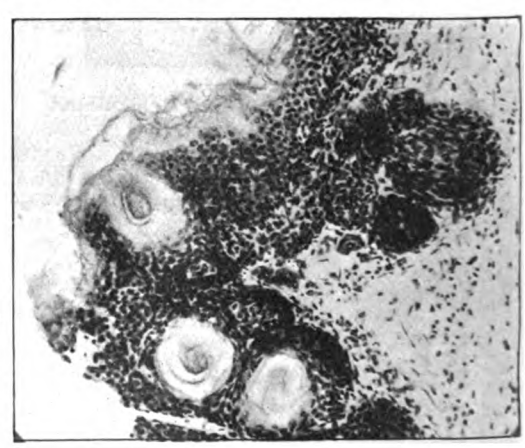

FIG. 71.—Buds of epithelial proliferation near the tumour.

was especially examined for the purpose. Many other rats from Villa Lagarina were infested with *Hepaticola*, but none with *Gongylonema*. With regard to this rat, therefore, *Gongylonema* seems to be definitely out of the question.

In and on the epithelium of the stomach around the tumour and on the tumour itself, a large number of worm eggs are visible in the sections. These

[1] *Zeitschrift für Krebsforschung*, pp. 207, 325. 1922.

eggs have an oval shape and at both ends they have a kind of plug in the thick eggshell (figs. 66, 67). Within the eggshell there is no larva visible, usually it contains one cell with a nucleus, that shows no signs of division (fig. 68). These are characters of *Hepaticola*.

In a series of sections near one side of the tumour, cross-sections of a worm or worms are present (fig. 70). Following up this worm in the serial sections, I can see that one worm is lying in an epithelial gallery, partly in the more or less normal epithelium of the stomach wall, partly in a gallery, very deep between the finger-shaped papillomatous excrescences of the tumour. The diameter of this worm, where it lies in the tumour, is about 50-58 microns. I cannot with certainty make out whether it is a young male or female.

In the epithelium of the stomach wall, near the base of the tumour, there are patches of epithelial proliferation. Small bud-like down growths of the epithelium are present at these spots. The muscularis mucosæ bulges out into the submucosa underneath these epithelial buds, but at other spots they invade the muscularis mucosæ and sometimes go right through it (fig. 71). The character of the epithelium, however, remains rather typical, and although one could not tell what would have happened, if the irritation at such spots had continued, it is obvious that, histologically, one is not entitled to speak of invasive tumour-growth at these spots. It is interesting to note, however, that we find here the same patches of heterotopical epithelial proliferation, that have also been described by Fibiger in *Gongylonema*-infected stomachs.

Discussion.

In comparing the histological changes present in the stomach of this rat with the changes in the stomach of Fibiger's rats, infected with *Gongylonema neoplasticum*, we are struck by a large number of similarities. The position of the worm in epithelial galleries is very much the same. The heterotopic invasive reaction of the epithelium is also described by Fibiger as very common in his rats. The presence of the papilloma with a secondary formation of an epithelioma resembles the formation of Fibiger's tumours in his *Gongylonema* experiments. The peculiar character of the tumour-cords in this *Hepaticola*-infected rat is not especially mentioned in Fibiger's work. In his descriptions as well as in the accompanying photographs, the tumours seem to be pure squamous-celled carcinomata.

Now that four cases of gastric cancer of the rat combined with the presence of *Hepaticola* have become known, it seems that *Gongylonema neoplasticum* should not be considered the only worm, capable of producing this pathological condition. Feeding experiments with *Hepaticola* are necessary to prove the rôle of *Hepaticola* experimentally. It is possible that *Gongylonema* may be a better agent in producing cancer than *Hepaticola*. Fibiger must have seen a very large number of *Hepaticola* rats without tumours. Wassink reports about ninety-nine rats from Amsterdam that were infected with *Hepaticola* in the stomach and did not notice anything worthy to be called a tumour. Still, on sixteen Surinam rats spontaneously infested with *Gongylonema*, Wassink found two well-developed papillomata, and recently I found myself one carcinoma, one large and five small papillomata amongst seventy-seven *Gongylonema*-infected rats from Surinam. But, besides the difference between the worms, other influences may be at work, causing differences in tumour-frequency in naturally-infected rats.

Summary.

In Villa Lagarina, a village near Trento, in Northern Italy, a wild rat (*Rattus norvegicus*) was found with a cancer of the cardiac portion of the stomach. The stomach harboured a nematode worm, *Hepaticola gastrica*. This is the fourth case described of the combined presence in the cardiac portion of a rat's stomach of a cancer and *Hepaticola*. It seems as if *Gongylonema neoplasticum* is not the only worm capable of producing cancer in the stomach of rats. In the same Villa Lagarina rat a mammary fibro-adenoma was present.

NOTES ON MYCOLOGY.

By J. Ramsbottom.

At the request of Dr. Sambon I joined his party for a period of a fortnight—afterwards extended to three weeks—with the object of investigating any mycological matter which might arise and of training Dr. Pan in collecting methods. Dr. Pan had worked with me for several weeks before we went to Italy, and had arranged to stay until the Commission left; I am indebted to him for his assistance while I was with the Commission.

As is stated elsewhere, the problem of the food of house beetles or of the possible presence of intestinal symbiotic fungi did not arise.

While investigations were being carried on at Villa Lagarina as thorough a search as possible was made in the houses where cases of cancer had been reported, and throughout my stay every opportunity was taken of examining the woodwork of houses. It is common knowledge that many fungi are quite frequent in houses, but the conditions met with in the Trentino were not such as would generally favour their presence.

Microfungi, e.g., *Stilbum erythrocephalum*, occurred commonly on rabbit pellets wherever these animals were kept, and the usual coprophilous Discomycetes and Pyrenomycetes appeared when the dung was kept moist for a day or two. *Chætomium* was frequent on bedding-straw and sterile white mycelia were present under practically all the boards which were lifted up in the stables; those examined invariably showed clamp connections, indicating that they belonged to Basidiomycetes. Such fungi were the only ones found above ground in the houses with the exception of a couple of rafters,

one at Villa Lagarina and one at an inn at Pelazzano, which showed the conidial stage of the common sulphur bracket fungus, *Polyporus sulphureus:* in these examples it is more or less certain that the fungus mycelium was already in the wood when it was first used. Otherwise no trace of fungal hyphæ was found on any such wood examined, i.e., rafters, flooring, doors, &c., except that occasionally coniferous wood showed the "blueing" characteristic of attack by *Ceratostomella.*

In a couple of houses at Villa Lagarina opportunity arose of visiting wine cellars. Both of these happened to be cancer houses, but it is not suggested that this is of significance. In the first house the cellar was cool, dark, and a little damp, though there was no standing water nor trickles down the walls. Wine barrels stood on heavy pine props which were said to have been piles of a bridge. Practically all over this wood an abundant fluffy white mycelium luxuriated, and collapsed when touched. This was obviously the aerial mycelium of *Merulius lacrymans,* the dry rot fungus. With the aid of the dull light from the single electric bulb—an amusing luxury when one considers the other domestic conveniences—supplemented by matches, it was possible to find the various stages of this fungus. As *Merulius* has often been regarded as a cause of human illness, it may be well to say a word or two about its habits. There are at least four varieties of the fungus, to which Falck has given the names *Merulius domesticus, M. silvester, M. minor,* and *M. sclerotiorum. M. domesticus* is the common species met with in houses. As the highest temperature at which it will grow is 80° F., this should acquit it from suspicion of causing human ailment in any direct way. This does not mean, however, that a house riddled with dry rot is desirable as a residence. The fungus is the most destructive fungus of worked wood known. It is mentioned in Leviticus as "Plague of leprosy in a house"—and in the days of the wooden walls of old England was the cause of much destruction in ships, as Pepys relates in his account of a commission of inquiry in the reign of Charles II. The fungus requires for its development a fairly warm, moist atmosphere, with little or no ventilation. The spores, though thin-walled, are long lived, and it is probable that a percentage of them are able to retain their vitality for several years. However this may be, they are rarely absent from houses where appropriate conditions for growth occur. On germination the spores put out a mycelium, which, having gained entrance into the wood, assumes two modes of growth. One type of mycelium ramifies within the wood and, living on the substance of the cell walls by the aid of enzymes, reduces it to a brown powder. The other type is superficial and spreads over the surface either as a thin whitish fish-skin-like film, or, when conditions are most favourable, as snow-like masses. As a result of the destruction of wood water is formed, and this is exuded by the fungus. The presence of these water drops explains the specific name of the fungus, but puzzles the lay mind in attempting to distinguish between dry rot and wet rot. These popular names are usually employed to signify whether the rot is in worked wood or unworked wood, i.e., whether the rot starts after seasoning, when the wood is dry, or whether it is present in the standing tree.

When growing in a confined space the film sometimes shows a yellowish tinge. The external mycelium apparently serves as a means of expansion over wood. In the cellar in which the fungus was first seen another type of vegetative spread was shown with textbook-like clarity. As the fluffy mycelium reached the walls and the ground it took on the film-like growth which passed into mycelial cords. These are at first white threads or strands with a somewhat floccose surface, and become grey or even blackish. It is by means of these cords that the fungus is able to spread from one source of food supply to another, passing through the mortar of brickwork, under tiles, and so on. Only the beginning of a couple of fructifications was seen. These show a honeycomb surface which becomes cinnamon in colour as the spores ripen and may be so much as a yard across. Millions of millions of spores are formed even by a sporophore of much more usual dimensions. Fructifications may appear on woodwork or even on walls. It is usually a sign that considerable damage has already been done when fruit bodies appear on woodwork; when they occur on material which provides them with no nutriment they are seen to be attached to the mycelial cords which conduct food from the seat of destruction. In the same cellar four other fungi were found: *Poria vaporaria* and *Fomes annosus* on the props and *Coniophora puteana* and *Trichothecium roseum* on the barrels. *Poria vaporaria* and *Coniophora puteana* are well-known dry rot fungi and are frequently found associated with *Merulius. P. vaporaria* forms a continuous persistent stratum and has a surface of large angular toothed pores which are at first white in colour and then cream. It possesses mycelial cords which remain persistently white. *C. puteana* forms a somewhat membranous flat expansion, the upper spore-bearing surface being smooth and at maturity a brownish olive colour with a white mucedinous border. It also possesses mycelial cords, but these are brownish and then blackish. The mycelial cords of the three species show differences in microscopical structure and are the most ready means by which non-fruiting stages of these fungi can be distinguished. *Coniophora* requires considerable moisture for its development, and it has been suggested that it is always the forerunner of *Merulius. Fomes annosus* is the *Trametes racidiperda* of foresters. It is of the polypore type, and is a most destructive parasite of conifer trees, attacking them at the roots and causing a "heart rot." It is a common fungus in mines, leading to great loss in pit props. It is able to develop fully in darkness, and does not form the bizarre sterile forms which some few fungi as *Lentinus* spp. and *Polyporus lucidus* affect in such situations.

The fourth species, *Trichothecium roseum,* is a harmless saprophyte, being the mould which shows

as pink masses in decaying organic material, as for example on badly dried herbarium specimens. The proprietor of the house stated that the props lasted only five or six years, after which time they could not support the barrels.

The second cellar was that of a wine grower. This was deeper than the first one, and unlike it was reeking with water. Here the logs on which the barrels were supported again showed the snow-like mycelial masses of *Merulius lacrymans*. We were told that the fungus had to be scraped away every week or that it would fill the place; the logs were said to last several years. Covering the walls there was a layer about a quarter of an inch deep of the black sooty growth of *Rhacodium cellare*, a harmless but unpleasant-looking saprophyte characteristic of such situations. At one place near the steps were found a few fruiting stages of *Merulius tremellosus*, a species common on pine branches. It was not possible, under the circumstances of the visit, to make out how the sporophores were connected with any wood.

In the surrounding country the vineyards were blue with Bordeaux mixture, which was liberally sprayed on the vines from knapsack sprayers. It was interesting to see the trouble that was taken to apply this fungicide, and to find out that invariably the cultivator knew the generic name of the fungus he was fighting against and could procure odd specimens for demonstration. All spraying at the time of our visit was against the downy mildew, *Plasmopara viticola;* dusting with sulphur against *Oidium* (*Uncinula necator*) was occasionally to be seen. Another disease which caught the eye was *Ustilago Maydis*, appearing on various parts of the maize plant, but particularly in the inflorescences as large greyish balls of which the thin outer membrane breaks to disclose a mass of dark brown powdery spores.

The smut of oats (*Ustilago Avenæ*) was common; also brown rust (*Puccinia triticina*) and black rust (*P. graminis*) of wheat. The alternate stage of this last species was exceedingly common on barberry in the Dolomites.

Several of the horticultural plants in the gardens at Villa Lagarina were covered with the oidium stage of mildews—roses, chrysanthemums, peas, &c.

The villagers are very fond of toadstools as food in the autumn, and dried fungi were to be seen in some of the shops at Rovereto. These appeared to be *Boletus edulis*. The common mushroom is apparently not a favourite with the villagers, judging from the remarks made when a coloured plate of this fungus was shown to them. The Italian curse that one may die of eating a *Pratiolo* suggested that this might be so. Apparently all the usual silvicolous fungi are eaten. In a restaurant at Milan the well-known esculents, *Amanita Cæsarea* and *Boletus reticulatus* were displayed, and later on in Trento, species of *Boletus*, *Cantharellus cibarius* and others appeared in the shops. The Trentino is classical ground for the larger fungi owing to the researches of the veteran mycologist, Abbé G. Bresadola, of Trento, whose acquaintance several members of the Commision had the great pleasure of making at his summer retreat at Varena, where he was actively continuing his researches.

While at Villa Lagarina a search was made through the gardens and vineyards adjoining the houses for the presence of crown gall. The result was disappointing. There was a single suggestive open canker on a rose bush, but although a large area of vineyard was traversed, no crown gall was seen. However, one learned that the disease was known to some of the growers, and an intelligent youth offered to find specimens for us; he produced a few small examples by digging somewhat recklessly at the roots of vines and an almond tree.

Observation was kept on the " geranium " plants (*Pelargonium*), which seem to be as great favourites with the villagers as is *Aspidistra* in this country. The only galls seen, however, were on experimental plants shown to us at the Serological Institute at Milan. Later we were shown good specimens on various trees at the Bacological Institute at Trento, and discovered others in the museum at the Agricultural College at San Michele. There can be no doubt that the disease is common in Northern Italy, but it was not possible to make search underground for it; its prevalence or otherwise on vines would best be ascertained at the time they are lifted, when a small monetary recompense would doubtless ensure specimens from a by no means unintelligent community.

The interest in crown gall has been considerable during the past few years, principally owing to the labours of Dr. Erwin F. Smith, the eminent American phytopathologist. He has published a series of papers during the last twenty years or so in which comparisons have been made between the appearances in crown gall of plants and human cancer. The following account is summarized chiefly from his writings.

Crown gall occurs as swellings or tumours on many cultivated plants and on some wild ones, usually at the collar or crown of the plant, though often at the roots or on the stems, and has been recorded from all over the world. The appearance of the gall differs according to the host plant, and may be hard or soft and of any size up to more than a yard in diameter. The cells of the host which are attacked are not killed, but are stimulated to multiply, the result being an imperfectly vascularized overgrowth composed in part at least of masses of rapidly dividing cells of reduced size. Attacked branches frequently are killed, but the whole plant seldom succumbs. The disease is of a peculiar type: (1) the growth is extra-physiological and injurious to the rest of the plant, slowly dwarfing or killing it; (2) secondary tumours occur as growths from tumour strands which are deeply embedded in the normal tissues, and derived by cell division in the form of a continuous chain of cells from the primary tumour; (3) the secondary tumours reproduce the structure of the tissues in which the primary tumour has developed even when they occur in other organs,

e.g., if the primary growth is in the stem and the secondary is in a leaf, the attacked part of the leaf will be converted into a pseudo-stem.

The growth of a tumour may stimulate multiplication of the surrounding uninoculated tissues.

The causal organism was first isolated and cross inoculations made by F. Cavara, Professor of Botany in the Royal University of Naples. It was named *Bacterium tumefaciens* by E. F. Smith and Townsend. It is a small, white, motile, rod-shaped organism with polar flagella, non-sporiferous, Gram-negative, non-acid fast, and grows on agar poured plates in the form of small, circular, somewhat raised, wet-shining, translucent colonies. It grows at from 0° to ± 37° C., the optimum temperature for growth being 25° to 30°. There appear to be at least three strains of the organism isolated from plants.

The bacterium has never been clearly demonstrated inside the tumour cells. According to Smith it "occurs only inside of certain of the proliferating cells. When the cell divides, the organism is carried over into the daughter cells, in at least a part of which it multiplies. It occurs in the cell in comparatively small numbers and, owing to the granular nature of the protoplasm, cannot be made out satisfactorily even with high powers of the microscope." The suggestion that human cancer might be due to some parasite endowed with similar chemical activities to *B. tumefaciens* has not been favourably received by the majority of botanists owing to the differences in structure between animals and plants; the absence of a circulatory system, in addition to a lack of a nervous and a central digestive system in plants apparently forbade legitimate comparison. The work of Professor Blumenthal, of the University Cancer Research Laboratory of Berlin, has, however, placed the matter in quite a different light. He claims to have isolated several times from human breast carcinomas a parasite in pure culture which is indistinguishable from *B. tumefaciens* obtained from plant tumours. Inoculated (either alone or with diatomaceous earth) into rats, mice, guinea-pigs, and rabbits, it produces malignant transplantable tumours which show in their histological structure the typical characters of sarcoma or carcinoma, growing to half the size of the animal and forming metastases almost as large as a walnut. In hot-houses and out of doors the parasite has repeatedly produced tumours on plants (especially sunflowers) indistinguishable from crown gall. The isolation from cancer is not easy, and only a small portion of inoculated animals have given persistent metastatizing tumours. Rat tumours are now in the eleventh and twelfth generation of transplant, the results being positive to the extent of 75 per cent. after the fourth transplant. Bacteria have not as yet been recovered from the transplants.

Such unexpected results have naturally aroused considerable scepticism. It should be stated, however, that Dr. Erwin F. Smith spent a fortnight in the Berlin laboratories and was convinced of the soundness of the investigations. "It begins to look, contrary to my belief hitherto, as if *B. tumefaciens* might occur frequently on or in man and be the cause of some of his cancer."

Assuming the correctness of this work, it remains to be seen whether the bacterium of itself is able to produce malignant growth in animals or whether it is the carrier of some ultramicroscopic virus; further, whether it is a special strain of *B. tumefaciens*, the cause of a world-wide disease of plants.

From the fact that *B. tumefaciens* has not been demonstrated with certainty in cells of plant tumours, it would be attractive to assume that it had an ultramicroscopic stage. Blumenthal (Auler and Meyer), discussing the reasons for the previous non-discovery of the human parasite, remark: "Gerade unsere Arbeiten mit dem *B. tumefaciens* bei Pflanzentumoren haben uns dazu geführt, beim Menschen am Rande des Tumors und in den erweichten Partien nach den Parasiten zu suchen." Recent work by Robinson and Walkden has shown that in certain cases at least of crown gall in plants, the bacteria which are located in the wounded surface and to some extent also in the vessels and adjoining intercellular spaces of the cortex are later present as a film on the rough outer surface of the gall. These results show the close similarity between crown gall and human cancer. There is growing conviction of the parasitic nature of cancer, but the whole gamut of pleomorphism, symbiosis and biological strains will doubtless be traversed in attempting to co-ordinate the results of recent researches.

ENTOMOLOGICAL NOTES WITH THE CANCER FIELD COMMISSION IN THE TRENTINO, 1925.

By K. G. Blair, B.Sc., F.E.S.

On the expedition to the Trentino district of Italy conducted by Dr. L. W. Sambon in July and August, 1925, the attention of the entomologists attached to the party was engaged mainly upon those insects that are known to be capable, or suspected of being capable, of acting as host in the early stages of the life-history of the Nematode worm, Gongylonema.

The insects thus observed fall into two categories, viz.: possible intermediate hosts of a Gongylonema that may attain maturity in man, and possible hosts of Gongylonema infecting domestic animals, particularly cattle and sheep.

Bearing in mind that for man to become infected with Gongylonema it is apparently necessary that the worm in its encysted stage should be swallowed alive by him, it is obvious that any insect liable to come in contact with human food is open to suspicion. This food may of course be such as is prepared and eaten indoors, or may be either carried outside or be gathered and consumed in the open. First, as regards food prepared and eaten indoors, it was known that at least two species of cockroaches, *Blatta orientalis* and *Blattella germanica*, occurred very generally in kitchens in the district, and considerable numbers were

collected, particularly from certain houses in which cancer cases had occurred, and were examined in our improvised laboratories for encysted worms. No trace, however, of Gongylonema was discovered in these cockroaches, though other parasites in some numbers were found. As the earlier cases of Gongylonema cysts to be found in these insects occurred only under experimental conditions, an attempt was made to repeat these experiments, and cockroaches of both the species mentioned were kept in confinement and as opportunity arose were fed with fragments of Gongylonema obtained from sheep and cattle at the slaughter-houses. These experiments, the details of which will be found in Dr. Baylis's report, were only partially successful, cysts of Gongylonema being later found in some of the smaller species of cockroach, though no trace of the development of the parasite was found in the more robust *B. orientalis*. Other insects found almost in all houses in which search was made in the flour bins were the common Meal-worm Beetle (*Tenebrio molitor L.*), occasionally found in the adult state, but much more often as the larva, and still more abundantly the Meal-moth (*Ephestia kuhniella*), again usually as the larva living freely in the flour or maize-meal, or spun up in the corners of the chest, especially above the level of the meal. Pupæ and a few adults were also observed. Although a considerable number of these larvæ were dissected and examined for Gongylonema, no trace of the worm was found, though a fairly high percentage, probably (accurate observations were not made) from 30 to 50 per cent. of the larvæ were attacked by one of its best known parasites, viz., *Nemerites canescens* Grav., a fly belonging to the parasitic Hymenopterous family, Ichneumonidæ. With the *Ephestia* larvæ were also the predaceous larvæ of the beetle *Tenebroides mauritanicus*. Other insects found in the kitchens were the Silver Fish (*Lepisma saccharina*) and some houseflies, but these, on account of the improbability of their ability to act as host to Gongylonema, were not particularly collected.

Other insects found not actually in the dwelling rooms of the houses, but sometimes in the ground-floor room, and also in outhouses and sheds in close proximity to the house, where chickens, and especially rabbits, were very frequently kept, were the Tenebrionid beetles, *Blaps lethifera* and *Tenebrio obscurus*. In both cases the larvæ were found occurring commonly with the beetles, and both species were frequently found together. They occurred in rather dry, dusty accumulations composed of earth, dried leaves, old straw, and rabbits' dung, this last usually more or less mouldy. As Gongylonema has already been recorded from other species of both *Blaps* and *Tenebrio*, and as rabbits' dung, possibly containing eggs of Gongylonema, obviously formed an important item in the diet of these insects, considerable attention was paid to them, but no trace of Gongylonema was found in either adults or larvæ.

Other insects found with them but in lesser numbers were the carabid beetle, *Sphodrus leucophthalmus*, which is predaceous upon *Blaps*, and a few smaller carabids, such as *Harpalus pubescens* and *H. griseus*, both occurring in quantity in the vineyards and gardens close by, and probably brought in with green maize and other fodder from outside.

Attention was also paid to the insect fauna of some of the village fountains. These fountains provide water for all domestic purposes, as well as for watering horses and cattle, and are usually arranged with a series of three troughs. The supply is in the form of a constant stream from a pipe line brought from some distance up in the mountains. From this supply water for domestic use, cooking, &c., is supposed to be taken direct, though in practice it is frequently dipped from the first trough into which this supply stream falls, and from which horses and cattle drink. The water in this trough is clear and well aerated, the sides clothed with green algal and mossy growths which harbour a number of different insects, as well as large numbers of a small pond snail, *Limnæa* sp. Water beetles, *Agabus nitidus*, and their larvæ were fairly numerous, as well as larvæ of certain Mayflies (*Bætis* sp.) and of such flies as *Chironomus, Psychoda, Pericoma*, &c., while on the outer walls of the trough, attracted by the moisture, were, in addition to the adults of the above-mentioned flies, such other species as *Orthoceratium virens* and *Elliptera omissa*.

From this trough the overflow supplies the second trough, which mainly serves for the final rinsing of clothes. The water here is more turbid with soap, though still fairly clear, and a few insects were still to be found in it. From this in turn the overflow supplies the third and much the largest trough, the walls of which have wide inward sloping slabs on which the soaping and kneading of the clothes of the village is carried out and the water in which is normally thick and turbid with soap, so as to be inimical to insect life. These insects from the fountains were not particularly examined for parasites.

Turning our attention to Dung-beetles, in connection with Gongylonema in cattle, these were collected in large numbers, and belonging to a fair number of species. Grazing ground in the vicinity of the villages is scarce, and is found mainly in narrow strips along the banks of the irrigating channels of the vineyards, and in some cases between the rows of vines, and the cattle here are usually found singly, and each beast, if not on a short tether, is in constant charge usually of a small girl or an old woman. Here and there is more extensive grazing of very rough nature, usually on a steep hillside encumbered with huge boulders and not good enough to be terraced for vines. It was on such ground that most of our collecting was done, every fresh cowpat being swarming with beetles. Most abundant of all was *Onthophagus taurus*, then probably the smaller shining red-spotted *Caccobius schreberi* and the more elongate *Aphodius subterraneus*. In smaller numbers were *Gymnopleurus sturmi*, the largest of the dung-beetles obtained in this way, *Oniticellus fulvus*,

Onthophagus opacicollis and *O. furcatus*, *Aphodius fimetarius* and *A. hæmorrhoidalis*, while occasional individuals of *Onthophagus nuchicornis*, *O. lemur*, *O. ovatus*, and *Aphodius erraticus* were also found. The larger dung-beetles, ***Ateuchus sacer***, *Copris* and *Geotrupes*, were not found at all, in the case of the first named possibly because the district was too northerly and beyond its range, in the case of the other two probably because it was a little too early in the season, a single specimen of *Copris lunaris* being found after the writer had left the party, while a number of *Geotrupes* on the wing fell into the car in the evenings. Most of these were dissected and examined for Gongylonema, and the sole example brought back was *G. mutator*; it is likely, however, that other very similar species were amongst the victims of the search for Gongylonema. With these dung-beetles were found a few other species of coprophilous habit, notably *Sphæridium bipustulatum* in large numbers, with a few Histeridæ, e.g., *Paçhylister inæqualis* and *Hister 12-striatus*, these latter two probably preying upon the larvæ of *Musca vitripennis* (Diptera), which were very abundant in the dung. A single example of *Emus hirtus* was also captured.

That these beetles were not restricted in their choice of pabulum to the dung of cattle was proved by the fact that most of them were as readily found in suitably fresh masses of human excrement on the same ground.

In several cases the dung in the sheds where Gongylonema-infested cattle had been stalled was examined for eggs of the worm, but without result, though in no case was the dung from the slaughtered animal positively identified.

Sheep were seldom seen except for occasional small flocks being driven along the roads, and there was no opportunity for collecting the dung-beetles associated with these animals.

Of the dung-beetles thus collected a fair number, about 4 or 5 per cent., proved to contain encysted worms of Gongylonema, as well as cysts of other nematodes. The beetles infected belonged to several species, e.g., *Onthophagus taurus*, *O. opacicollis*, *Caccobius schreberi*, *Oniticellus fulvus*, and *Aphodius subterraneus*; in fact practically every species of which sufficient individuals were examined appeared to be capable of allowing the development of Gongylonema. So far so good, but there still remains the question, how does the Gongylonema return to the cattle? For, in order to become infected, the cattle must swallow the encysted worm from the insect. Most of these dung-beetles shun the light, and when turned out of their cowpat make all haste to bury themselves in it again, or if unable to reach it quickly burrow down into the earth. The chances, therefore, of a feeding cow accidentally swallowing one of them would appear to be somewhat remote. One of these species, however, *Aphodius subterraneus*, was on one or two occasions observed out in the open, once crawling

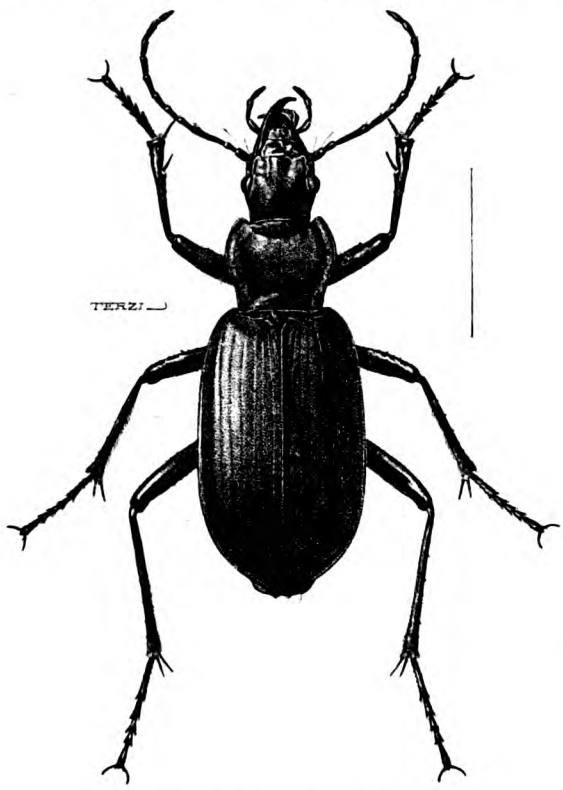

FIG. 1.—*Sphodrus leucophthalmus.*

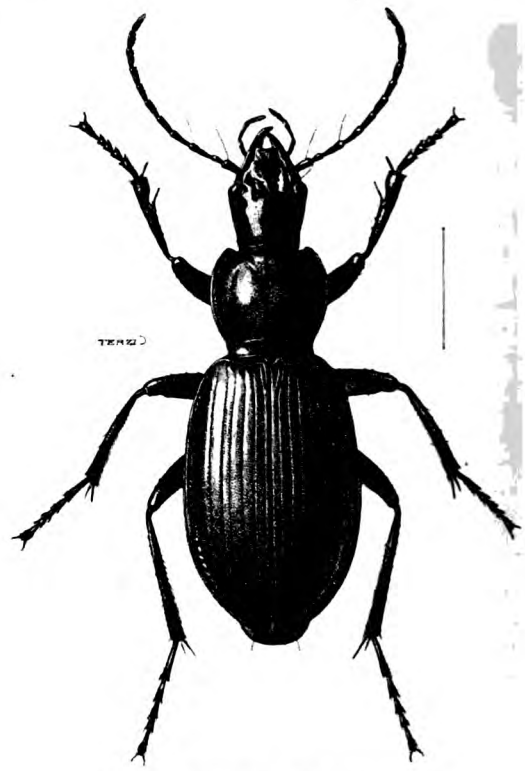

FIG. 2.—*Pristonychus terricola* ♀.

on the edge of a trough in the village, and once resting on a grass blade. Other species of *Aphodius*, particularly perhaps *A. contaminatus*, fly readily in the sunshine and are frequently observed crawling on herbage, so it would seem that some species of dung-beetles stand perhaps a greater chance of being swallowed by a grazing cow than others. Is this chance sufficiently great to acount for the high percentage of cattle from these areas found to be infested with the worm?

Another possible method of contracting infection is connected with the fact that if the encysted worm be placed in water it will rupture the cyst-wall and escape into the water. An infected dung-beetle may drop into a stream, or be flooded out of its cowpat after a storm and drowned, and on the decomposition of the body encysted worms would be liberated in the water and readily swallowed by man or beast drinking at the stream. It is by some such method of infection that the Gongylonema worms in the mouth of the girl swine-herd of Rome seen by Dr. Sambon were probably contracted.

Of insects other than those connected with the life history of Gongylonema a number of interesting species were observed. A large proportion of them were species common enough at home, though some very conspicuous species, e.g., amongst the butterflies, *Papilio podalirius* (and less commonly *P. machaon*), *V. antiopa*, &c., would cause some excitement if seen in this country. The male Gypsy Moth (*Ocneria dispar*) was not uncommon, dashing about over waste ground. This species was evidently kept well in check by parasites, the poplar trunks in the hotel garden providing numerous remains of young larvæ accompanied by single cocoons of a braconid parasite, though many of these cocoons produced only the hyperparasitic chalcid *Monodontomerus obscurus*. A bunch of eggs of the gypsy moth only produced *Anastatus bifasciatus*, which pretty little chalcid was bred also from a bunch of eggs of an unidentified pentatomid bug, while other groups of empty egg-shells of the same bug appeared to have produced the same parasite.

The telegraph poles on the road from Rovereto to Villa Lagarina were suffering badly from the attacks of a Longicorn larva, some of them appearing in imminent danger of falling, while the capture of two specimens of *Hylotrupes bajulus* sitting on the poles gave a clue to the culprit. Other interesting beetles of this group were *Ægosoma scabricorne*, a single specimen at rest on a lime trunk, *Spondylus buprestoides* flying in the hotel garden, *Criocephalus rusticus*, two specimens both ♀ taken at light, as also were two ♀ examples of the handsome melolonthid, *Polyphylla fullo*. The fine *Purpuricenus kaehleri* was found paired on a bush bordering a vineyard, while *Clytanthus varius*, *C. sartor*, *Leptura rubra*, *Strangalia attenuata*, *Grammoptera bifasciata* were swept from flowers in the gardens or vineyards.

A small sandy flat bordering the River Adige produced some poor grazing, and various insects in addition to dung-beetles; the runs of the Mole Cricket were much in evidence, while one or two of the insects were discovered, and other corpses were awash at the water's edge. A few *Cicindela hybrida* were captured with some difficulty, while the staphylinids *Pæderus gemellus* and *Stenus longipes* (?) were not uncommon. The little caddis-fly, *Oligocentrum maculatum*, was fluttering in numbers over the water, and the leaves of a small fig tree growing in the embankment near by were black with it. A number of large tabanids appeared to be not unwilling to transfer their attentions from the cattle to ourselves, but paid for their presumption with their lives.

On rough grassy ground *Mantis religiosa* was not uncommon, but mostly immature until August had well set in. The peculiar *Homorocoryphus nitidulus* was found in moister or more shady situations, but was also immature; a pink variety was found in addition to the usual bright green form. At night the small cricket, *Gryllus burdigalensis*, was very noisy by the roadsides, but it was not easy to track the noise down to the singer, nor to extract him from crevices in stone walls when found. Occasionally a specimen would be turned up by day under heaps of garden rubbish. Other long-horned grasshoppers taken included *Tylopsis lilifolia*, resembling our *Leptophyes punctatissima*, *Metrioptera albopunctata*, one female bearing numerous red acari between the wings, and *Decticus verrucivorus*, which, as its name implies, was at one time employed to bite away warts in the belief that this treatment would prevent their recurrence.

Odonata were but little in evidence except by the lakeside at Levico, where *Orthetrum cancellatum*, *Ischnura elegans*, *Platycnemis pennipes*, *Agrion lindenii*, &c., almost certainly *Anax parthenope*, were abundant. This fine æschnid with a conspicuous blue patch towards the base of the abdomen evaded capture. The handsome *Onychogomphus forcipatus* was taken by Lake Garda.

Of neuroptera the most striking were myrmeleonid larvæ, ant-lions, found in several places; from these *Myrmeleon formicaleo* emerged after our return home. The somewhat similar pits formed by the larvæ of the leptid fly, *Vermileo*, were found on ledges of walls at Villa Lagarina. *Ascalaphus* was not seen, unless a number of empty yellow eggshells arranged along a grass-stalk can be assigned to this genus.

Of Rhynchota some twenty species were collected of which probably *Pyrrhocoris aptera* was the most conspicuous, occurring in vast numbers and in all stages on walls, tree trunks, especially limes, and on the grass. Around Rovereto and Villa Lagarina the Cigale, *Cicada*, was very noisy, but with the exception of a few seen out of reach up in the trees we could not discover the songsters.

Besides the few Diptera already mentioned, captures included the fine *Stratiomys chameleon* and *Volucella zonaria*.

Stomoxys calcitrans was a considerable nuisance at Rovereto, but the pain caused by its stab soon passes away without leaving persistent irritation. Another interesting biter, both indoors and out, in the evening, was *Phlebotomus papatasii*. Mos-

quitoes were hardly seen, but were not worked. An *Anopheles maculipennis* was noted biting on the train as we left Venice.

On tree trunks here and there large, white, silky-looking patches were observed which, on investigation, proved to be a woody encrusting fungus covered with the shining web spun by the larva of a mycetophilid fly. From some of these larvæ the fly, *Sciophila ochracea*, was subsequently reared.

Hymenoptera, besides the parasitic species already mentioned, included such forms as *Ammophila*, *Cerceris*, *Scolia*, *Polistes gallicus* with nests, *Eumenes*, *Scelephron*, and others, mostly from flowers in the gardens. A nest of hornets was observed in a hollow lime tree, but was not investigated for scavenger or parasitic beetles. Ants, mostly *Lasius niger*, with some *L. umbratus* swarmed around the lights of the restaurants at night and were crawling all over the tables beneath them.

In all about 250-300 species of insects were noted, about 100 of which were Coleoptera. For a month's stay this is not a long list and includes little in the way of rarities, but it must be remembered that opportunities for general collecting were not very numerous owing to our work keeping us for the most part either in the villages or their immediate neighbourhood, or in the laboratory working at the material collected. From an entomological standpoint the best country was merely passed rapidly through in the car on some of our longer excursions, with no time to stop and sample the insect fauna of the vicinity.

EXAMINATION OF CANCEROUS AND OTHER TUMOURS IN ANIMALS COLLECTED BY DR. SAMBON DURING HIS RECENT RESEARCHES.

By Sir G. Lenthal Cheatle, K.C.B., C.V.O., F.R.C.S.

Surgeon and Lecturer in Surgery, King's College Hospital.

Acting as consulting pathologist to the Tropical Disease Prevention Association, I have carefully examined the pathological material submitted by Dr. Sambon, together with his Report on cancer field researches recently made in Italy and Holland. The results of my examinations fully agree with the statements he has advanced regarding the same.

Liver of Rat with Cyst of *Strobilocercus fasciolaris*.

A cyst in which is included a bladder-worm. In one corner of the cyst part of the larval cestode is embedded. At this point the tissue in which the strobilocercus is embedded is a large spindle-celled tumour the blood-vessels of which are in a very unorganized state. In one part of the section there is a piece of liver against which part of the tumour described impinges, pressing together the walls of blood-vessels. At this point there is no actual invasion of liver tissue. In other parts of the tumour there appear to be collections of cells which look like liver cells, as if the tumour had invaded the liver and destroyed part of it.

Kidney of Rat with Worm-Cyst.

A multi-locular cyst completely surrounded by renal tissue except one part, where a tumour consisting of epithelial cells is bulging into one of the loculi of the cyst. The epithelial cells of the tumour resemble renal epithelial cells. In no part is there invasion of normal renal tissue, but the tumour seems to be pressing it on one side. In the tumour itself the epithelial cells are collected in masses that vary in size from a collection of about forty or fifty cells to large collections of innumerable cells, and both the large and small clusters are separated from each other by fine strands of delicate connective tissue.

Stomach of Rat with Malignant Papillomatous Growth.

In this cancerous wild rat found by Dr. Sambon in Villa Lagarina, Italy, were two tumours: a benign breast fibrous tumour and a papillomatous tumour growing from the walls of the cardiac portion of the stomach. This papilloma is definitely malignant. The slides of this neoplasm prepared by Dr. Bonne, a member of our Field Commission, show that the epithelial cells have invaded a blood-vessel in which the elastica has been stained, and there is no doubt that it is a blood-vessel that has been invaded by carcinoma. In the connective tissue of this malignant papillomatous tumour can be seen a nematode worm (*Hepaticola gastrica*) in cross section and another similar worm at the base of the growth. Scattered over the walls of the stomach are the characteristic lemon-shaped eggs of this parasite. Hence I agree with everything Dr. Bonne has described in his contribution to the Report.

Rat's Breast Tumour.

Judging from the size of the sections and from the macroscopic size of the mammary tumour in the Villa Lagarina rat, the microscopical sections appear to be slices of the whole breast. There is no suggestion of epithelial proliferation, but the connective tissue surrounding the lobules, around the ducts and around the acini, has undergone very marked proliferation. In some parts the proliferation is more marked than in others, giving rise to the impression that there has been a generalized fibro-adenomatosis of the breast. No worms can be seen in these sections.

Original Communication.

CONCERNING THE DISCOVERY OF THE PLAGUE BACILLUS.

By E. LAGRANGE, M.D.Liège, D.T.M.Paris.

Former Assistant of Dr. Yersin in Nha-Trang (Indo-China).

THE wide publicity given to an article on "The History of Plague in Hong-Kong," by A. G. Millott Severn [1] led us to review a point which appears to be obscure. We have reviewed original papers, in order to clear up this misunderstanding.

The matter is not without interest, in view of the many contradictory opinions which have been advanced and which shall be discussed directly.

In June, 1894, Kitasato, then head of a Japanese Commission, and Yersin, a French doctor, came to Hong-Kong to study plague. Within an interval of a few days both claimed that they had discovered the ætiological agent.

These two young promising scientists had already a glorious scientific career behind them.

In 1894, when Yersin was 31 years old, he had already collaborated with Roux in 1887-1888 on the classical communication on diphtheria and its toxin. After several months' travel in the Far East, as a physician in the Merchant Marine in the South China Sea or as explorer in French Indo-China, being in Saigon he was sent to Hong-Kong by the French Government to investigate the new epidemic.

In 1887, Kitasato isolated and cultivated the bacillus of tetanus, and in 1890, with Behring, demonstrated the antitoxic properties of the antitetanic serum. When he returned home in the splendour of the Meiji, he soon found himself at the head of the bacteriological movement in Japan.

These were the two investigators who opened the fight against the terrible plague. Their communications have been published in various journals. Our purpose is to examine them carefully and to determine who was really the discoverer of the plague bacillus.

* * *

Although Europe was for a long time free from plague, the disease was endemic in South-Western China.

Aoyama [2] has shown that plague was diagnosed in 1884 in Pakhoi; that it was endemic also in Yunnan and Mongolia. At the time of the epidemic in Hong-Kong in 1894, Yersin nearly escaped being sent there for bacteriological studies. The first cases of plague appeared in May, 1894, in Hong-Kong amongst the Chinese community. The disease was already prevalent in Canton (about 100 miles away), and when Dr. Lawson, the British Health Officer, was sent there, he was soon called back to Hong-Kong to face a widespread scourge.

On June 12, Professor Kitasato and Aoyama arrived at Victoria, each of them with an assistant and a medical student, who joined the Commission.

On June 15, Dr. Yersin, a doctor in the Colonial Service, arrived alone.

* * *

The activities of the Japanese Commission have been related in a most interesting paper by Aoyama, who was in charge of the clinical and anatomical investigations.

He describes the general conditions of the city and the locations of the hospitals. After a fortnight, he and an assistant came down with plague, which they contracted at a post-mortem examination.

Three hospitals were set aside for plague patients at the beginning of the epidemic. A floating hospital was reserved for the Europeans; the second was a Chinese hospital under the care of Chinese doctors, and finally the Kennedy Town Hospital, a former police station, was under the care of English doctors.

Here the two scientists were allowed to perform post-mortem examinations. Later on, these hospitals became insufficient for the needs, and abandoned glass works, "un bâtiment affreusement délabré," a new slaughter-house under construction, and finally a straw hut, officially called Alice Memorial Hospital, were employed to receive the sick.

A very poor arrangement, according to Aoyama; no beds, no blankets, no mosquito-nets available; and mattresses only for Indians and Japanese. A photograph reproduced in Aoyama's paper shows the half-naked patients lying in a large warehouse, where numerous mosquitoes entered at night.

Even to-day the Chinese quarters of Victoria City strike the European tourist by their filthiness. From 165,000 to 250,000 people, according to different census, were huddled together under the worst conditions; filthy houses, foul-smelling streets, bad or no sewers; everything seemed arranged for the best conditions for the spread of plague.

Kitasato arrived on the 12th and started work on June 14 [3]; at an autopsy, performed by Aoyama, at the Kennedy Town Hospital, numerous bacilli were found in an inguinal bubo and in all the viscera. But owing to the fact that the autopsy was performed eleven hours after death, he doubted the specificity of the bacilli. He also cultivated and inoculated the bacterium into mice. On the same day he examined the blood taken from the finger of a case with an axillary bubo, who had a temperature of 40·5 (105° F.), and found an encapsulated bacillus, resembling the bacillus of chicken cholera.

Although he doubted the reality of his discovery, the local papers, the same day (June 14), published Professor Kitasato's discovery of the plague bacillus. The papers stated that the bacillus was a long rod, abundant in the blood of patients who had died of the disease.

The next day Yersin called upon Professor Kitasato and found him making an autopsy. He was surprised to note that Kitasato paid no attention

to the bubo, but simply examined the blood and the spleen. According to Yersin's diary, it was only later on that Kitasato was advised by Dr. Lawson to examine the buboes.

However, Kitasato cultivated and inoculated his bacillus, and noticed that all the laboratory animals, except pigeons, were killed within one or two days following the inoculations. At death he found the bacillus in all the organs.

On August 11 *The Lancet* published a short editorial "from the notes of Dr. Lawson of Hong-Kong." The paper is illustrated with four drawings; one is a specimen of human blood stained by Kitasato which shows several bacilli (?) to about fifty red cells; a preparation of Kitasato's culture which shows similar elongated diplococci; and a fourth on which was a preparation of the spleen made by Lawson. As far as one can decide from these drawings, the bacteria appear to be pneumococci. This diversity in morphological appearance did not escape Kitasato, and he says: "The organism—which is a bacterium resembling the bacilli found in the hæmorrhagic septicæmias, except that the ends are somewhat more rounded—when stained lightly appears more like an encapsulated diplococcus, but when more deeply stained, it has the appearance of an ovoid bacillus. . . . When, however, it is focussed more accurately, it is still possible to see the diplococcus form."

This was the first description of the Kitasato bacillus: a very short one indeed. On August 25 *The Lancet* published Kitasato's report on his first researches [3]. He claims that the bacillus is found in the blood, the buboes, the spleen and the viscera; that it is a rod with rounded ends with bipolar staining. "I am at present unable to say whether or not 'Gram's double-staining method' can be employed. The bacilli show very little movement." The optimum temperature for the growth varies from 36° to 39° C.; the culture in broth appears turbid; the writer states he did not observe either the growth on gelatin or the presence of spores; he also notes the results of animal inoculations. On this Kitasato's claim rests; it is the only basis of his claim to priority.[1] But the fact that he could not decide upon the reaction to the Gram stain and that he observed the motility of the bacterium, shows that he was in doubt between several bacilli which were present in his slides and cultures, and that he could not separate or distinguish them apart. It seems that Kitasato was in a hurry to publish his first results.

We have to see further what he says in regard to the manner in which the bacillus reacts to the Gram stain.[2]

Aoyama's paper [2], published the next year, tries to elucidate this point. In sections made from buboes, he finds in association with the "Kitasato bacillus" [*sic*] micrococci and streptococci. The "plague bacilli" and the micrococci decolorize by Gram's method. "Aus der Verschiedenheit der Gestalt und der Färbarkheit der Blutbacillen mittelst der Gram'schen Methode glaube ich, dass sie von den Lymphdrüsen nicht identisch sind. Wenn die Streptococcen sich von den Ketten ablösten und zu zweien aneinender fügen, so ensteht das ähnliche Bild des Blutbacillus. Da die Streptococcen meist in den Blutgefässen der Lymphdrüsen anzutreffen waren, so vermuthe ich das die Blutbacillen von Kitasato weiter nicht als im Blute circulierende Streptococcen aufzufassen sind."[3]

This is the statement of Aoyama, who was associated with Kitasato in Hong-Kong. It is seen, then, that one year later he does not consider Kitasato's bacillus as the bacillus of plague!

If such is the current opinion in the Japanese scientific circles, it is evident that the work of Kitasato had not been accepted.

Let us follow Kitasato's next publications—after this "preliminary notice" and his official report.

The next communication [5] was written in Japanese in 1897, and is not to be obtained here. But in 1898 another communication appeared in which the writer gives a detailed description of "his" bacillus.

"In 1894 a scientific commission for the investigation of plague, directed by Aoyama and Kitasato, was sent from Japan to Hong-Kong, where the writer (Kitasato) was able to isolate the bacillus which is the specific cause of the malady." He then adds that the bacillus is not decolorized by Gram's method. "They are endowed with motility which is not very active, but which should not be mistaken for molecular movement. In order to observe their motility it is best to study them in a medium at the temperature of 37° C." Kitasato found this organism 25 times in 28 cases in blood preparations after finger puncture.

The article ends as follows: "It has been quite generally assumed that the bacillus above described is identical with that of Yersin, but this assumption is incorrect. The two are quite distinct, as

[1] These two articles in *The Lancet* as well as the statements in the local press in Hong-Kong explain the mistake of Dr. James Cantlie, who was in Hong-Kong at the time. In 1898, during a discussion of a report of Arnott ("Pathology of Plague"), Cantlie states that Kitasato and Yersin have been wrongly grouped as the co-discoverers of the plague bacillus. He states that Kitasato discovered the bacillus a week before Yersin, and although he has a great esteem for Yersin's work, he thinks that he cannot be considered as the "original discoverer of the bacillus." That distinction belonged to Kitasato alone. *Brit. Med. Journ.*, 1898, ii, September 24, p. 862.

[2] As soon as he returned to Japan, Kitasato published his official report in the *Japanese Official Journal* of August 30 and September 1, 1894. Ogata [9] has shown that Kitasato did not publish the same facts in this and his next papers. While in his second paper of 1897 (see below) Kitasato notices the presence of glands in the inoculated animals, in this first report he only notices a bacillus whose inoculation does not produce glands and which kills the animal, only after two to five days. Kitasato hence contradicts himself.

[3] "As the bacilli present in the blood differ in size and staining properties by the Gram method, I think that they are not the same as those present in the glands. When the streptococci are broken from their chains and are liberated, they may produce the appearance of the blood bacilli. As the streptococci are mostly present in the blood-vessels of the lymphatic glands, I think Kitasato's blood bacilli need to be considered as streptococci circulating in the blood."

may be seen from the following summary of their differences." Kitasato then cites the differences already published by Ogata, and he concludes at the time when Yersin had already prepared his serum (1896): "Further bacteriological investigations of plague are desirable." The following year another opportunity presented itself; during another Japanese epidemic, Kitasato continued in his error [7]. To quote: "Beside the pest bacilli, like those of chicken cholera, *staining deeply by Gram's methods*, staphylococci and streptococci were seen." Still, other investigators had already demonstrated his mistake in regard to the Gram stain with striking clearness.

Zettnow [8], in 1895, was able to make the comparison between the cultures received from Metschnikoff (probably of Yersin's bacillus) and slides sent by Kitasato to Koch. He took photographs of them. In a heart-blood preparation the Kitasato bacilli look quite like pneumococci; while those from Metschnikoff's cultures show the typical bipolar staining.

M. Ogata [9], in 1897, was greatly opposed to Kitasato's views and added: "Ausserdem sollte mann auf Insekten wie Flöhe, die infolge der Abkühlung der verendeten Ratten diese Tieren verlassen und das Pestgift direkt auf den Menschen übertragen Können, achtgeben."[1]

This is the first time attention was drawn to the important part of fleas in the transmission of the disease.

Metschnikoff, in 1897, although well versed in the literature, wrote as follows [10]: "Yersin après des recherches laborieuses effectuées dans des conditions particulièrement difficiles, découvrit le microbe pesteux. Indépendamment de lui, Kitasato arrivait au même résultat."[2]

And amidst all these contradictory opinions, Kitasato issued no further contributions on the subject; and yet most of the textbooks have called the plague bacillus the bacillus of Kitasato-Yersin.

In 1923, in an article by Kitasato on the scientific and medical development in Japan, he attributed the discovery of the plague and dysentery (Shiga) bacilli to Japanese scientists.[3]

However, in 1925, as chairman of the Congress of the Far Eastern Medical Association, before 400 members, amongst whom were 250 foreign delegates, Kitasato is to be honoured for having publicly stated that Yersin alone was the discoverer of the plague bacillus.

* * *

Through the courtesy of Dr. Dujardin-Beaumetz, head of the plague laboratory of the Pasteur Institute of Paris, we have been able to see some valuable documents concerning Yersin's studies in 1894.

Besides the slide here photographed, the official report of Yersin to the Governor of Indo-China and his unpublished and private diary were seen.

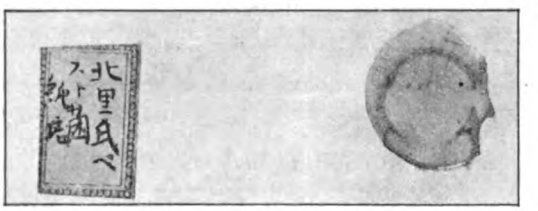

FIG. 1.—Slide presented by Kitasato to Yersin. The text reads as follows: Mr. Kitasato; plague bacillus, pure culture; staining by fuchsin; many germs are grouped by twos, and are difficult to recognize whether plague bacilli or pneumococci.

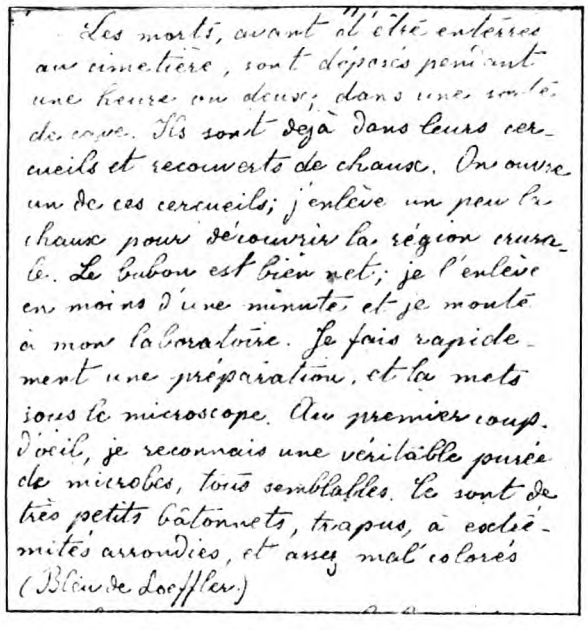
After many difficulties, Yersin finally arrived at Hong-Kong on June 15, 1894. He had an Annamese servant who had been with him in his exploration of Indo-China, and a Chinese servant who was engaged in Haïphong before he sailed.

His laboratory equipment was meagre: a sterilizer and some material to prepare media, but no incubator. He did not speak English. The French consul was alone and hence was unable to accompany him. Fortunately, he had an introduction to an Italian missionary, Father Vigano, a former soldier at Solferino, who helped him greatly.

FIG. 2.—Yersin's hut close to the Alice Memorial Hospital.

At the Kennedy Town Hospital, Yersin met Kitasato, who was performing an autopsy. The conversation was difficult as Yersin knew only a few words of German; they had no other common language.

During the first days at the hospital he could not obtain any autopsies; he was informed that they were reserved for the Japanese Mission. He had



[1] "Besides, one should pay attention to insects like fleas, for as the rat becomes cold after death they leave their host and may transmit the pest virus direct to man."

[2] "Yersin discovered the plague bacillus after painstaking research made under very difficult circumstances. Independently, Kitasato obtained the same result."

[3] We regret that we cannot indicate the reference to this statement. In 1924, while sailing through the Pacific on a Japanese steamer of the Toyo-Kisen-Kaisha line, we had the opportunity to read a book describing the most important points of interest in Japan. It is a book (in quarto) with English text, abundantly illustrated, edited, 1924, by the Toyo-Kisen-Kaisha line. Despite a painstaking search we have been unable to find this book in Paris.

to content himself with the examination of blood from patients. He found no bacteria there. His laboratory was an open porch, with an easy access to any passer-by.

He finally decided to erect a straw hut near the Alice Memorial Hospital, where he worked and

Les morts, avant d'être enterrés au cimetière, sont déposés pendant une heure ou deux, dans une solution de chaux. Ils sont déjà dans leurs cercueils et recouverts de chaux. On ouvre un de ces cercueils; j'enlève un peu de chaux pour découvrir la région crurale. Le bubon est bien net; je l'enlève en moins d'une minute et je monte à mon laboratoire. Je fais rapidement une préparation, et la mets sous le microscope. Au premier coup d'œil, je reconnais une véritable purée de microbes, tous semblables. Ce sont de très petits bâtonnets, trapus, à extrémités arrondies, et assez mal colorés (Bleu de Loeffler).

FIG. 3.—From Yersin's diary.

lived. This was rather daring when we think that at that time both he and Kitasato believed that the plague was transmitted from man to man by mosquitoes and flies, as Yersin finally demonstrated to be the fact. Let us quote from his diary:—

"June 20. I have to-day paid several visits to obtain the permission to erect a straw hut near the hospital. I have again been refused the autopsies; as before, I was told that to morrow it would be my turn. In the meantime, I have satisfied myself that the plague bacillus is not chiefly in the patient's blood. I hope to be more successful by examining the bubo. But I cannot extirpate the buboes, as I cannot obtain autopsies, at least at the police stations. With the help of Father Vigano, I try to persuade some English sailors, whose duty it is to bury the dead from the city and the other hospitals, to let me take the buboes from the dead, before they are buried. A few dollars conveniently distributed and the promise of a good tip for every case have a striking effect. The bodies before they are carried to the cemetery are deposed for one or two hours in a cellar. They are already in their coffins in a bed of lime. The coffin is opened, I move the lime to clear the crural region. The bubo is exposed, within less than a minute I cut it away and run to my laboratory. A film is prepared and put under the microscope; at the first glance, I see a real mass of bacilli, all identical. They are very small rods, thick with rounded ends and lightly coloured (Löffler blue). From the bubo I inoculate agar tubes, mice and guinea-pigs. I take some secretion in a pipet to send it to Paris, and then return to the mortuary and try to obtain new cases. I obtain two other buboes with similar results. My bacillus is most probably that of plague, but I am not certain.

"June 21. . . . I go on cutting and examining buboes. I always find the same bacillus, extremely abundant. My animals inoculated yesterday are dead and show the typical plague bubo. . . . As I cannot obtain autopsies, I decide to address a claim to the Governor by way of the Consul.

"June 23. . . . In the future, I will obtain one autopsy of two. I may start one at once. I notice that there are no other constant lesions except the bubo in the cases of acute plague. The bacillus may be found diffused, but the chief location is always the bubo. . . . I try to collect as many cases as possible for the Pasteur Institute of Paris. I always take the secretion of the buboes in small glass tubes which I regularly send to France by mail. . . . I search and find the organism in the corpses of dead rats, and there are many throughout the city. . . ."

After a short stay at Canton, and as the epidemic was near its end, Yersin, considering his object fulfilled, left Hong-Kong on August 3 for Saigon. On July 30 E. Duclaux, director of the Pasteur Institute, read extracts of letters from Yersin before the Academy of Sciences [11] announcing in very definite terms the discovery of the bacillus of plague. The following September, Yersin's first paper was published in the "Annales de l'Institut Pasteur," with very clear photographs of the organism. The bacillus was very demonstratively described. The same paper was reprinted in October in the "Archives de Médecine navale et coloniale."

After a short stay in Paris, where, in collaboration with Calmette and Borrel, he succeeded in immunizing small laboratory animals [12], Yersin sailed again in 1895 for the Far East. He immunized horses against plague in Nha-Trang (Annam), while at the same time this was being done at the Pasteur Institute in Paris. Armed with sera, he went to Hong-Kong in June, 1896, and later to Canton, where he made his first trial with serotherapy on a young Chinese boy belonging to the Catholic Mission.

With 30 c.c. of serum he succeeded in curing his first case within less than 24 hours.

From there he went to Amoy, where of 23 treated cases he cured 21 [13, 14].

The Yersin bacillus of plague was hence demonstrated.

Yersin prepared his original serum by injecting living bacilli, but now this procedure has been abandoned owing to its danger. (Personal communication.)

NOTES ON THE USE OF ESERINE IN GLAUCOMA.

By B. C. VACHHRAJANI, L.M. & S., B.M.S.,
Medical Officer Thar Parkar Civil Hospital, Mirpurkhas.

AS showing the value of eserine in the treatment of glaucoma, the following notes of cases, treated in the course of the work of the Blind Relief Association here, either in the civil hospital or by the touring medical officers of the Association, may be of interest.

Mianbai, wife of Piral (aged 45), of Phuladhi, in Taluka Khipro, seen in November in the village; glaucoma case. Had practically no vision, but treated in the camp with eserine, four grains to one ounce. Pupils contracted and vision improved at once, and after the third day's treatment she was able to see the tent. Unfortunately, as the camp was moving, she did not follow it up as instructed, and was not seen again.

Umar Bilawal Mangrio (aged 30), of Khami Mangrio, in Khipro Taluka. Glaucoma in left eye; right destroyed. On January 21, 1926, he had little more than perception of light. After one treatment vision greatly improved, but field remained very much contracted on the nasal side; did not follow up the camp, but was later brought to the civil hospital, where eserine treatment was continued, with the result that the field greatly improved. The man absconded before the treatment was completed.

Mulo Chanio Vagir (aged 40), of Chor, in Umarkote Taluka; glaucoma in both eyes; no sight in right eye, a little sight in left eye; field very much contracted on nasal side, and vision only at the extreme side of the field; was treated with eserine, four grains to one ounce,, for several days, and the field rapidly improved, till he had vision in the centre of the field and even further. As a test, the treatment was dropped for two days, and then he began to complain of a little headache and loss of field was noted. He was again put on eserine and the field again improved. Operation was suggested; he absconded and has not been seen since.

Sono Kesaro Bhil (aged 30), of Mithi Taluka; glaucoma in both eyes, with dilated pupils, especially in the right; had good sight in left eye; in right only perception of light. Treated with eserine (4 gr. to 1 oz.) on 14th, 15th, 16th and 17th February. Both pupils contracted at once. The perception of light in the right eye improved almost at once; on 16th he could see with that eye a white handkerchief and fingers within a few inches. On 17th he saw fingers at 10 ft. with that eye. Discontinued treatment, but later again turned up and eserine treatment was continued and ultimately trephining was done. No subsequent report yet to hand.

Two cases are reported from the Bijapur district of patients with glaucoma and no sight. Both recovered sight after constant eserine six times a day. One was seen again after a year and the sight was quite good. In one, and best of these cases, there was not even P. L. originally.

Generally here the instillation of eserine is given two or three times a day and the strength is 4 gr. to 1 oz.

The results indicate that eserine is a most valuable drug and should be given a good trial before operation. In one case at least where an operation was done first and eserine instilled afterwards, no improvement took place.

A NOTE ON FURTHER EXPERIENCES OF THE USE OF A PANAMA HAT IN TROPICAL AFRICA.

By J. F. CORSON.

IN a previous paper (1926) a few experiments to test the protective power of a Panama hat as a substitute for a helmet in tropical Africa, were recorded. The climatic conditions during the period of these experiments were comparatively mild and somewhat guarded conclusions were given. Opportunity has occurred since to make use of a Panama hat under much more severe conditions of exposure to the sun's rays. This form of hat has been worn exclusively during the last five months, viz., from November, 1925 to March, 1926, and during the latter half, from January to March, in the district of Musoma, on the eastern side of Lake Victoria. This district has an altitude of about 4,000 ft. above sea level and, in the parts traversed, is open hilly country with granite rocks and is sparsely wooded. There was little rain during the period, the sky being usually clear and the sun's rays strong enough to cause severe blistering of the exposed skin of the face, arms and legs. Circumstances involved travelling by dhow, canoes, bicycle and on foot during the hottest hours of the day until 3, 4 and 5 p.m. No unpleasant effects, that could be attributed to the action of the sun's rays on the head, were experienced either during exposure or afterwards. During long marches, the comfort of the light hat contrasted with the discomfort felt on many previous occasions when wearing a Wolseley helmet. It would not have been practicable, nor was it thought necessary, to make meteorological observations, the purpose being to test by practical experience. The protective power of pigmentation of the skin of the face, forearms and knees is well known to all European residents in the tropics accustomed to

travel, and it is possible that similar pigmentation occurs in the skin of the scalp under conditions of limited transmission of ultra-violet rays.

Conclusions.—A Panama hat has been found to be an efficient substitute for a helmet in tropical Africa under conditions involving exposures for several hours during the hottest part of the day. There is no reason to think that there are great individual differences in people in relation to this question but, until more general experience is available, nothing definite can be said as regards this. It may be suggested that additional comfort, by loss of heat, would be gained by making guarded ventilation apertures at the sides of the hat.

Blood-Transfusion in Pernicious Anæmia (H. W. Jones, *Journal of the American Medical Association*, May 29, 1926).—Thirty patients were treated by transfusion; twenty are living; there were ten deaths. Of the twenty living, the time that has elapsed since transfusion varies from a few weeks to seven years. The time elapsing from the date of the first transfusion varies from two months to seven years. In five patients the blood has been brought to a normal count three times. In four patients the blood has been brought to a normal count twice. Thirteen of the twenty patients are performing at least a part of their duties. One patient in whom marked nervous phenomena developed was brought to a normal blood-count three times in a period of fourteen months. Death resulted from pyonephrosis. Hæmoglobin and red blood-cells were practically normal at that time. One patient died of pneumonia. The blood-count was normal. One patient with a blood-count nearly normal died of a hæmolytic reaction. One died because it was impossible to get further donors for him. His blood-count had been brought to normal twice. One patient refused more transfusion after being brought to a normal count twice. One patient, after being brought to a normal count twice, died six hours after transfusion given at the beginning of the third relapse. One died two days after the first transfusion. This is the only patient whom it was not possible to bring to a normal count at least once with transfusions when donors were available. In order to accomplish good results, the following points must be observed: a small amount of blood (100 c.c.) should be given at the first transfusion to offset the possibility of death in a very few cases, unless the patient requires a larger amount to carry him past the danger point. Whole blood should be used. Moderate amounts of blood, from 350 to 450 c.c., should be given. In the hæmolytic stage, the amounts should be increased daily, beginning with 50 c.c. The transfusion should be employed at four-day intervals.

THE TREATMENT OF CANCER BY LEAD.

THERE can be no doubt that in the whole range of medical science there is no subject of greater interest or more pressing importance than the investigation and control of malignant disease provides. Blair Bell looks upon malignant neoplasia in the human subject as a biological atavism and considers that a considerable degree of parallelism exists between the cancer-cell and that of the chorionic epithelium. Further, a comparison between the chemical constitution of different tissues in regard to the factors concerned in growth-processes demonstrates clearly not only that malignant tumours are richer in this respect than the corresponding normal structures and innocent neoplasms of the same parts, but also that the physiologically malignant chorionic villi show

even higher values than pathologically cancerous tumours; the chorionic epithelium may thus be considered to be super-malignant. If, then, any substance could be found which would exert a selective destructive action on the cells of the chorionic epithelium, devoid of deleterious action on other tissues, it would seem reasonable to suppose that a similar selective destructive action would be exerted upon cancer cells and so bring about a cure of the neoplasm.

From quite ancient times the occurrence of sterility and abortion in animals and man in association with lead poisoning has been well known, and so widespread is this knowledge at the present time that in some districts, at any rate, lead is extensively employed by women as an abortifacient. The method by which this action of lead was brought about was thought to be by the production of hæmorrhages into the placenta as into the other organs of the body.

The experimental investigations of Blair Bell and his colleagues in Liverpool, however, have shown that lead causes specific abortion by its lethal action on the chorionic epithelium, with the production of a coagulation necrosis—a result which they were unable to obtain by the use of other metals, such as copper, thorium and thallium. On account of this selective activity for the chorionic epithelium abortion can be produced by the action of lead on the fœtal ectoderm (trophoblast) without the maternal organism being affected in any way, and it was found that the effective abortion dose of lead is approximately half the lethal dose.

Influenced by these analogies attempts have been made to treat cases of malignant disease by the administration of preparations of lead. For this purpose colloidal suspensions have been prepared and intravenously injected. Clinical work on these lines has now been in progress in Liverpool for about four years, and the type of case in which treatment has been conducted has been very varied, including carcinomata and sarcomata in all parts of the body. The cases were for the most part of a very desperate character, a large number having died within a few weeks of being seen for the first time. On the other hand, in some instances even hopeless cases, proved microscopically, have recovered under the treatment and are alive and apparently well to-day.

Some day it is hoped that a substance less toxic than lead to the organs of the patient, and even more effective than this metal in arresting and destroying cancerous tissue will be found, and then the hope that malignant neoplasia may be subject to control will have become an accomplished fact.

Annotations.

Depopulation of the New Hebrides and Other Parts of Melanesia (P. Buxton, *Transactions of the Royal Society of Tropical Medicine and Hygiene* February 18, 1926).—The people of the New Hebrides, and indeed, of Melanesia in general, are dying out. To some extent this is due to the constant wars, the belief in magic, the bad housing, the unsuitable feeding of infants, the treatment of women, the practice of abortion and other customs, all of which prevailed in the old days, and still prevail to a large extent in most parts of the group. But though one must bear the existence of all these facts in mind, one cannot regard them as directly responsible for the depopulation (which has set in during the last century), because the customs have prevailed from time immemorial. The majority of the Europeans who were in the group during the nineteenth century were trading either in sandalwood or in human beings. They are directly responsible for a great number of kidnappings and deaths, and they brought with them epidemics which sometimes carried off as much as a third of the population of an island in a few weeks. The credit for stopping this and rousing the public conscience in England and the British Dominions belongs, mostly, to the Presbyterian missionaries; but they are also in part responsible for the dying out of the people, because they rapidly destroyed the communal life and interests of the race, and put next to nothing in the place of what they destroyed; this was pointed out by Rivers several years ago, but what he wrote does not appear to have affected the policy of this mission. The fact that the government is a condominium makes administration very slow and uncertain, so that it is at present too difficult to suppress illegal recruiting and the sale of alcohol to natives. At the time of the author's visit, no free medical assistance for the native race was provided by the condominium. The system of recruiting is a compromise, perhaps necessary, between the interests of the natives and the planters. It is believed that it could be abolished if indentured labour were introduced. Among the endemic diseases, malaria and yaws are of major importance, because they render the race unhealthy and liable to succumb to introduced epidemics. They must only be regarded as two among many factors, all of which affect the question of depopulation; malaria is entirely absent from one island, but the population of that island has declined rapidly from other causes. Of the introduced diseases, dysentery and pulmonary disease are of very great importance. Apart from all these factors two very disquieting facts have been discovered. The rate of decline of the population of most islands is no less now than it was half a century ago; the race continues to die out, irrespective of the abolition of the "blackbirding" and of reduction in severity of epidemics. In all parts of the group about 118 males are born per 100 females, and this disproportion persists

through life. The continued decline and the excessive production of males almost warrant one in saying that the eventual extinction of many of the races now living in the New Hebrides is inevitable.

Malarial Fevers in the U.S. Army and at Selected Stations (A. G. Love, *The Military Surgeon*, July, 1926).—One hundred years ago malaria fevers were responsible for more than 25 per cent. of all admissions from disease to Army hospitals. Since the World War it has been responsible for only 1 per cent. In 1841, during the Seminole War in Florida, 50 per cent. of the admissions to post hospitals were charged to it, all admissions to the field hospitals being omitted from consideration. During the Mexican War it was apparently responsible for about 25 per cent. of the hospital admissions, and during the decade following for about 24 per cent. During the Civil War 23 per cent. of the admissions from disease were charged to malaria and it was only second in importance to the ever-present diarrhœa and dysentery. Among the white troops it caused 70 per cent. as many admissions as diarrhœa and dysentery, and among the coloured troops 100 per cent. as many. During the decade following the Civil War, 25 per cent. of the admissions from disease were due to this cause. This was the result in part of the stationing of the greater part of the Army in the south. This percentage was reduced to 10 per cent. during the decade preceding the Spanish-American War. During the Spanish-American War and the Philippine Insurrection, among the white troops in the U.S. malaria was responsible for 23 per cent. of admissions from disease; and during the World War for only one half of 1 per cent. The Army experience during both the Civil and World Wars indicates that fewer cases of malaria occur among the coloured troops than among the whites, but the fatality rate for the coloured is higher. In addition to the deaths and loss of time from the cases admitted to hospitals on account of these fevers, there was formerly much chronic invalidism and loss of military efficiency as a result of physical unfitness, which cannot be measured by vital statistics.

In certain sections of the country, a great deal was accomplished by what might be termed natural causes in the reduction of the prevalence of these fevers prior to 1900, when the mosquito was first definitely incriminated as being entirely responsible for the dissemination of these fevers. But the general reduction did not occur until after the introduction and continued application of intelligent anti-mosquito measures, with the protection of the mosquito from the infected individual and of the individual from the infected mosquito. Some of the measures used since 1900 are: drainage, oiling of all standing water; screening of all barracks, quarters, and especially of hospitals; thorough treatment of all malarial patients during both the acute and chronic stages; use of mosquito nets for the troops in the field and in barracks when screens are defective. Civic improvement and the bringing of waste and marshy areas under cultivation.

Military Service in the Tropics, and its Effect on Health and Efficiency (J. F. Siler, *The Military Surgeon*, July, 1926).—The present day Army regulations of the United States prescribe the following lengths of tour in tropical possessions: Philippine Islands 2 years, with extension if physically fit and applied for by the individual; Panama 3 years, and Hawaii 3 years, on the same conditions. A study of the records for the past 20 years shows that there have been marked reductions in the sick rates for white troops in the Philippine Islands from epidemic diseases, but the progress made in the control of the same group of diseases in the United States has been even more satisfactory. Comparatively speaking, therefore, health conditions have not changed in so far as general admission rates for epidemic diseases are concerned. The rates for venereal diseases are being reduced, but not nearly so satisfactorily as is the case in the United States; the rates for malaria are now at so low a point as to be of minor importance; the rates for the dysenteries are now much lower than was the case in the early years of the occupation; the dengue rates have remained at a consistently high level, but a very radical reduction in these rates may be anticipated in future years; and the rates for tuberculosis in the Philippine Islands are considerably higher than in the U.S. In so far as epidemic diseases are concerned, an extension of the tour of duty will not adversely affect the health of troops except possibly in the case of venereal diseases and tuberculosis, provided the responsible authorities will apply efficiently the known measures for the control of this group of diseases. The rates for other general diseases, such as tumours, rheumatic fevers, nutritional diseases, the anæmias, diseases of the glands, alcoholism, &c., have been lowered, but the reductions made in the U.S. have more than doubled those attained in the Philippine Islands. So far as diseases *per se* are concerned, troops on duty in the Philippine Islands are not now so subject to seriously disabling diseases as was the case in the early years of the occupation, and the present tour of duty (two years) could be prolonged by six months to not to exceed one year without material injury to health and efficiency of the average individual. Prolongation of the tour beyond a period of three years is considered inadvisable, and if extended to two and a half to three years, the regulations governing leave and detached service should be very liberal.

Studies on Urobilin Physiology and Pathology. The Relation of Biliary Infections to the Genesis and Excretion of Urobilin (P. D. McMaster and R. Elman, *The Journal of Experimental Medicine*, June 1, 1926).—Experimental infection of the incubated and previously sterile biliary tract of the dog with particles of the stools leads to a formation of urobilin from the bilirubin of the bile as it flows through the ducts. No urobilinuria occurs, how-

ever, unless temporary biliary obstruction is produced, or the liver parenchyma injured. Then urobilinuria develops, despite the fact that no bile is reaching the intestine and, by corollary, no urobilin being formed there. Cholangitic urobilinuria as one may term the phenomenon just described, to distinguish it from the urobilinuria having origin in pigment absorbed from within the intestine, is far more pronounced in animals possessing a healthy gall-bladder or with one prevented from functioning by severance of the cystic duct. These facts suggest that there may be an active absorption of urobilin from the normal gall-bladder. There can be no doubt that the pigment is absorbed from within the bile ducts. There is no evidence whatever to justify the belief that urobilin is ever formed through the action of the liver parenchyma. There may conceivably be an intralobular formation of the pigment consequent upon the activity of bacteria within the liver tissue, though such a happening has yet to be demonstrated.

The Geographical Distribution of Spontaneous Encephalitis in Rabbits (E. V. Cowdry, *Journal of Experimental Medicine*, June 1, 1926).—The author's observations seem to justify the hope that the obstacle afforded to experimentation by the frequent presence of spontaneous encephalitis and nephritis in American and European rabbits does not exist to the same degree in rabbits from certain other localities. The observations are, furthermore, despite their obvious limitations, in conformity with the theory that the disease is not one common to domestic rabbits everywhere, but rather that it occurs in special localities from which, given favourable conditions, it may spread. Thus far it has not been reported in tropical climates or south of the Equator.

Generalized Alopecia. Report of Three Cases with one Necropsy (G. Wilson and N. W. Winkelman, *Journal of the American Medical Association*, May 8, 1926).—Three cases are cited as examples of generalized alopecia. In the first the condition came on one year after a complete hysterectomy, with the coincident occurrence of symptoms that were due to brain tumour. The fact that removal of the ovaries usually produces hypertrichosis and also that the alopecia did not occur until one year later would militate against the possibility that the condition was ovarian in origin. The situation of the brain tumour directly over the pituitary and in the third ventricle produced erosion of the sella turcica which, with the low blood-sugar and hypotension was suggestive of a disturbance of function in the region of the infundibulum or pituitary, or both. In the second cases, the symptoms came on after severe emotional stress and here, too, there are symptoms referable to the pituitary region, although not necessarily a tumour. It is said by some that emotional stress is incapable of producing such a marked disturbance of a ductless gland, yet exophthalmic goitre has been known to develop in a woman shortly after she had been nearly drowned. Furthermore, the so-called neurocirculatory asthenia or effort syndrome which in certain cases may be of endocrine origin occasionally comes on after severe fright, and in this group of cases disability persists for many years. Other cases of universal alopecia following emotional stress have been recorded; thus Sabouraud described a case of profuse alopecia in a girl aged 13, who lost her hair thirteen days after being raped, although the hair returned later. Boisser, Bidon and Morris have all cited cases of generalized alopecia coming on after severe emotional stress. The cause of the alopecia in the third case is unknown. In this case, as in the second one, various glandular extracts were tried over a period of one year but without results.

Abstract.

SMALL-POX AND CLIMATE IN INDIA. FORECASTING OF EPIDEMICS.[1]

By Sir L. Rogers.

The small-pox incidence in India is greatest and most uniform from year to year in Madras, the only province not receiving much rain during the south-west monsoon months from June to October.

In all the seven provinces receiving the south-west monsoon rains there is a remarkable decline of small-pox every year at that season, followed by an increase during the ensuing cold and hot dry seasons once more checked by the next monsoon In Madras there is no decline of the disease at that season in the absence of the south-west monsoon, and only a very slight fall after the October rains, while the main small-pox rise occurs after the heavy rains of November and December. The rainfall of all three months is derived from the north-west autumn monsoon. Rainfall alone will not, therefore, explain the great fall of small-pox in the rest of India during the south-west monsoon.

The greatest small-pox epidemics occur in the low rainfall areas of north-west India and the central Indian and Deccan plateau, while they are least marked in humid Bengal with consistently high rainfall; the epidemics in the former areas nearly invariably follow a greater or less failure of the south-west monsoon rains, accompanied by comparatively low humidity.

The provincial average small-pox incidence shows no relation to the monthly temperature, and none to the relative humidity in the damp areas of Lower Bengal, Assam and Madras. The absolute humidity (that is the amount of aqueous vapour as measured by its pressure, a convenient measure of combined humidity and temperature) shows a close relation to small-pox prevalence. It rises to its maximum with the annual decline of small-pox during the south-west monsoon in every province receiving its main rain then. In Madras both the

[1] Abstracted from Report No. 106, Medical Research Council, July, 1926.

absolute humidity and the small-pox rate are stationary at that season in the absence of the south-west monsoon, while the maximum absolute humidity occurs as early as April and May and is accompanied by the annual moderate early decline of small-pox. The early winter north-east monsoon rains occur during a fall of the mean monthly temperature and of the absolute humidity, thus explaining their failure to prevent the winter increase of small-pox in Madras. The influence of high absolute humidity in checking small-pox thus suffices to explain its seasonal prevalence in all parts of India with their very varying rainfalls and temperatures.

A map shows increased small-pox with decreased rainfall and absolute humidity in northern India from Bengal to the north-west frontier province; it is especially noteworthy that in the latter area alone is the absolute humidity during the south-west monsoon as low as in Madras, as this is the only climatic feature common to these distant parts of India, and that the small-pox rate is nearly as high.

Records of small-pox case-incidence in Indian jails for thirty years—the data of which are recorded in areas selected for their meteorological conditions—show a very close relationship between high annual humidity and low small-pox incidence, and vice versa, in the whole of northern and central India, once more confirming the influence of humidity.

The effect on the yearly variations of small-pox mortality of meteorological conditions has been studied from monthly charts of the rainfall for forty-eight years, and of the absolute humidity for thirty years, for which they are available for eight provinces of India, and also the yearly small-pox rates and absolute humidities during the monsoon and autumn for thirty years; with the result of showing that in the less rainy areas of the north-west and central India, with average absolute humidity during the monsoon of about 0·700-0·800, low absolute humidity during that period is nearly always followed by excess of small-pox in the ensuing dry seasons; while in the areas with heavy rainfall of Bengal and Assam, as well as in Madras, the absolute humidity during the summer, which is very high, reaching 0·800-0·970, has very little relation to small-pox incidence, but years in which the humidity is low in the autumn, when normally it ranges from about 0·700-0·800, are generally followed by excess of small-pox in the ensuing dry months. The only exceptions are that low humidity soon after a small-pox epidemic, which has exhausted most of the susceptible material, may not result in any increase of the disease; while five or six consecutive years of normal or high absolute humidity may be followed by a rise of small-pox, on account of the accumulation of susceptible persons.

By watching the absolute humidity in India, and possibly in other tropical continental countries, at the season when they normally average about 0·700-0·800, about four-fifths of small-pox epidemics may be foreseen two or three months ahead, in time to enable the public health authorities to issue warnings and to organize additional vaccination staff to cope with and minimize the approaching outbreak of small-pox.

Current Literature.

BULLETIN DE LA SOCIÉTÉ DE PATHOLOGIE EXOTIQUE. *April* 14, 1926.

Spirochætal Pulmonary Affections of Madagascar (E. Tournier).—Certain pulmonary syndromes exist in Madagascar due to Castellani's spirochæte or one very similar. The spirochæte is found in large numbers in the sputum; it is easily stained in watery solutions of fuchsin or methylene blue. It has never been found accompanied by fusiform bacilli or other microbes, and cannot be classified with fœtid bronchitis or pulmonary gangrene. Three different types of clinical syndrome have been observed: (1) Type of hæmorrhagic bronchitis, with abundant hæmoptysis; little or no fever, bronchial râles, slight dyspnœa, rapid cure. (2) Syndrome of pulmonary congestion, shivers, high fever with irregular temperature, well-marked dyspnœa, general condition serious. Moist râles. The mucous expectoration is always hæmorrhagic without presenting the characters or abundance of the hæmoptysis of hæmorrhagic bronchitis. In these cases complications are often observed and diarrhœa is frequent from secondary enteritis due to deglutition of the sputum. (3) Asthma. This affection, very frequent in Madagascar, presents the identical symptomatology of the adult European affection. Spirochætes have been found in the sputum of all the patients suffering from asthma. The specific treatment by arsenicals is very effective. The best method is subcutaneous or intramuscular injections of novarsenobenzol; minimum dose 0·30 cg., injection to be repeated every three or four days. Treparsol has given very good results in a case of asthma; and enteritis responds well to stovarsol and to treparsol.

The Coccidiosis of Domestic Animals in Russia (W. L. Yakimoff).—Several species of Coccidia have been found in the stools of domestic animals of Russia, in the district of Lodeinoe-Pole. Bovine coccidiosis begins in spring and lasts until autumn, and very often terminates fatally. Autopsy shows hyperæmia of the intestine, sometimes rectal ulcerations. Infection is due to drinking from stagnant waters. Coccidiosis of sheep, probably due to *Eimeria faurei*, is frequently observed, and the affection also exists among goats, pigs, fowls and vipers. This is the first report of coccidiosis in Russia.

Coccidiosis of Pigs in Russia (W. L. Yakimoff, W. J. Wassilewsky, E. N. Markoff and E. F. Rastegaieff).—During September and October, 1924, the intestines of 91 animals at Petrograd were examined

for coccidia; 39 were found to be infected. In October and November of the same year, 13 pigs were examined in the Crimea; 5 were infected. The coccidia were ovoid in form, rarely spherical, and resembled *Eimeria stiedæ*. The same forms have been observed by Cauchemez, with a micropyle which was not observed in these cases. The examination of the bile and liver gave no results. Some authors do not believe that these coccidia are pathogenic to pigs; in this paper the authors do not come to the conclusion that they are pathogenic, as the animals were obtained from slaughter houses, but constipation and desquamation of the cells have been observed in infected animals. The coccidia incriminated as the cause of the disease in pigs is *Eimeria debliecki* Douwes, 1921.

The Rôle of Gastric Juice in the Natural Immunity of Rabbits in Coccidiosis (T. A. Kolpakoff).—Coccidiosis in rabbits is very frequent in Petrograd, especially in very young animals. It rages during summer and autumn and the mortality reaches a percentage of 80. These investigations show that the gastric juice of rabbits hinders the sporogony of *Eimeria stiedæ*. The sporogony does not take place in the gastric juice or intestine or in the bile. The very young rabbits are the most susceptible to disease, and the best prophylactic measure is to separate the young ones from the mothers.

The Use of Larvicidal Powders against Mosquitoes (E. Roubaud).—Larvicidal powders have given very good results in these experiments and are considered very promising. Most of them can only be successfully used under favourable conditions. They have many advantages over oils and liquid larvicides against mosquitoes, which are not practicable for using in larger areas and very often render the water temporarily unusable. The powders, being insoluble, cannot contaminate the water and are easily disseminated by the air. The author describes in detail the action of trioxymethylene, arsenical powders and a proprietary substance. The latter is the one most highly recommended against anophelines and culicines, especially for use on a large scale; its action is rapid and lasting and harmless to other forms of life. When used against anopheline larvæ, the powder is spread on the surface of the water; against culicines it must be held in suspension to reach the larvæ feeding below the surface; in each case paralysis of the larvæ ensues, resulting in death. The toxic action of trioxymethylene is not lasting, and applications should be made once a week in hot weather and every ten or fifteen days in cold weather; the applications should not be made oftener than this or the larvæ will become immune to its action through frequent small doses. The disadvantage of this substance is its high cost.

Calcium arsenite, copper aceto-arsenite, arsenic trisulphide and copper arsenite were among the arsenical powders which proved efficacious, but their action does not last longer than that of trioxymethylene.

The proprietary substance, of which the active principle is formaldehyde, has been prepared in a peculiar medium chosen to counteract the effects of moisture, and to increase the floating capacity or the maintenance in suspension of the powder. It is more lasting in effectiveness than the others, and its action is more rapid.

Sleeping Sickness in Portuguese Guinea (J. Sant Ana Barrets).—A first case of sleeping sickness has been recorded in Portuguese Guinea, where *Glossina palpalis* is abundant, but where the disease has not hitherto been observed. The patient was a European who evidently contracted the infection from some immigrant or traveller from equatorial Africa.

Treatment of Sleeping Sickness by Tryparsamide (S. Abbatucci).—Tryparsamide is considered the best medicament in the treatment of sleeping sickness in the second period of the malady, but should not be used during the first stage as it very frequently causes ocular troubles.

The Pathogenicity of "Bouffissure" in Annam (J. Kerandel).—Great importance is attached to the study of this malady, which is somewhat grave and frequent and is the principal cause of mortality in Annam. It has been attributed by various authors to ankylostomiasis, malaria, beriberi, &c. It is characterized by general œdema; the swelling begins in the lower limbs, spreads to the upper limbs and finally the whole of the body is affected. Anæmia is a constant symptom; the liver is atrophied, spleen hypertrophied. When the œdema disappears in the course of treatment the patient becomes extremely thin. Ankylostomiasis is not the cause of this disease, but it aggravates it. This affection is not common to all ages; it is very rare under 12 years, and few cases have been observed in people over 31 years. Syphilis appears to play an important rôle in "Bouffissure," but the real cause of the disease is still obscure.

Medical News.

LONDON SCHOOL OF HYGIENE AND TROPICAL MEDICINE.

PRESENTATION TO DR. ANDREW BALFOUR.

MANY members of the teaching staff of the London School of Hygiene and Tropical Medicine and other friends, including Lady Manson, assembled in the library on Friday, July 23, in order to make a presentation to Dr. Andrew Balfour, the Director. The presentation took the form of a picture by Mr. A. O. Lamplough, representing a Sudanese on a camel in a waste of sand. At the same time Mrs. Balfour was presented with a silver rose-bowl as a memento of the occasion. The presentation was made by Professor R. Tanner Hewlett, who said:—

"Dr. ANDREW BALFOUR,—We are gathered here to-day to make you a little presentation as a token of goodwill and esteem in which you are held not only by your colleagues of the School, but by many other outside friends. If you will look at the list of those who have contributed to this presentation you will find that it includes a representative of the Rockefeller Foundation, past and present members of the teaching staff of the School, members of the staff of the Tropical Diseases Hospital, representatives of the Seamen's Hospital Society,

members of the Bureau of Hygiene and Tropical Diseases, and of your administrative staff (and in this connection Mr. Harris writes to say how sorry he is to be unable to be present to-day and how proud he is to serve under you). Many years ago—more years probably than either you or I care to reckon—I had the honour and pleasure of being present at a dinner to bid you farewell on your approaching departure for Khartoum.

"I little thought then—a score of years or more—that I should, in the future, be the unworthy mouthpiece of those who desire, in a sense, to welcome you back again in the important and honourable post of Director of the London School of Hygiene and Tropical Medicine. I need hardly say how glad I am to do this and appreciate the call, though I am bound to say I suspect it is a somewhat dubious compliment to myself based on length of service and grey hairs rather than on actual merit!

"We have now reached what may, perhaps, be regarded as the third stage in the career of the School of Hygiene. The first stage was the noble gift of the Rockefeller trustees of funds for the foundation of the School. The second stage was the altogether admirable appointment of yourself as Director of the School, and the third stage was initiated the other day by the laying of the foundation stone of the permanent home of the School.

"Some of us of the old London School of Tropical Medicine, so successful in the past under the ægis of the Seamen's Hospital Society, to whom a warm tribute ought to be paid for their wisdom and foresight in undertaking so desirable, though at the same time so great, a venture, some of us of the old Tropical School may feel some regret at its disappearance as a separate entity, for, believe me, under the inspiration and leadership of Sir Patrick Manson we throve wonderfully and were a very happy family. But all of us, I think, agree that the incorporation of the Tropical School in the new School of Hygiene was a right and proper step, and we, in particular, members of the old Tropical School, welcome your appointment as Director because we believe that the great Mansonian tradition will be worthily maintained in your hands as regards the tropical side of the School's activities.

"As regards other activities of the School, in your hands, too, we may rest assured that they will be in equally safe keeping. The physical side of health training certainly will, for have you not won, if not spurs, at least many hacks and bruises on university and international football fields? You have experience of public health administration, you have travelled widely and have a broad outlook on health problems, you are a research worker and know the importance of a live school combining teaching with research. When I look at the list of decorations and degrees you have acquired, of the prizes you have won, of the appointments you have held, of the campaigns in which you have taken part, and of the committees upon which you have served, I begin to ask myself: Has Scotland produced only one Admiral Crichton?

"Moreover, by your silver speech and ready pen you do much for the School. Was not the last-named (your ready pen) partially trained in the realm of romantic fiction? We may be sure you will not be 'Cashiered,' may we hope that your course will be a smooth one, not determined 'By Stroke of Sword' nor recourse 'To Arms,' and that in your present post you have in some degree entered into 'The Golden Kingdom.'

"This little gift which we have for you I beg you to accept, firstly, as a welcome (somewhat belated perhaps) to the School; secondly, as an appreciation of all you have done for the organization of the School activities and of the inauguration of its permanent home; and thirdly, as a token of cordial esteem and goodwill from colleagues and other friends. It may also serve to remind you of the time you have spent in tropical climes in the service of humanity and of your country.

"Finally, it is a pleasant supplement to the presentation to yourself to ask Mrs. Balfour, your closest colleague, kindly to accept this rose-bowl as a memento of this occasion."

Dr. Andrew Balfour, in reply, expressed his thanks and those of Mrs. Balfour for the presentations. He referred to the welcome he had received from the Staff of the School who had rendered him all the assistance possible in the task of reorganizing the School. He paid a warm tribute to the great qualities of Sir Patrick Manson, and said that he for his part would do all in his power to maintain the Mansonian tradition.

QUESTIONS OF PRIORITY CONNECTED WITH MALARIA.

Sir Ronald Ross wishes us to announce that he will be glad to show original papers on this subject if anyone interested in them will write to him at the Ross Institute for Tropical Diseases and fix dates for the visit. Some of these publications can apparently be no longer obtained, and seem to be still unknown to various writers on malaria. Any date will suit him if fixed beforehand. The Institute is reached by General Omnibus Service 51 in ten minutes from Putney Bridge Underground Station.

THE GOLD MEDAL OF THE AMERICAN MEDICAL ASSOCIATION.

The Gold Medal of the American Medical Association for 1926 has been awarded to Professor Aldo Castellani for his work on Tropical Mycoses.

New Preparations, Inventions, &c.

Sodium Salts of Tetrabrom-phenolphthalein and Tetraiodo-phenolphthalein.

Burroughs Wellcome & Co. are in a position to supply sodium salts of tetrabrom-phenolphthalein and tetraiodo-phenolphthalein for use in cholecystography.

These salts may be obtained in gelatin capsules for oral administration or in glass containers if intended for intravenous injection. Medical men should state the strength required when ordering.

Medical bacteriologists may be interested to know that Burroughs Wellcome & Co. are in a position to supply sodium salts of the following organic acids: *d*-tartaric, *l*-tartaric, *meso*-tartaric, citric, fumaric and mucic. These agents are now being employed in the differentiation of bacterial types in which "sugar reactions" are untrustworthy or fail altogether. Further particulars may be obtained on application to Snow Hill Buildings, London, E.C.1.

The "Agla" Micrometer Syringe Apparatus.

The accurate instrument for the measurement of extremely minute quantities of liquids, described by Dr. J. W. Trevan in *The Biochemical Journal*, xix, No. 6, p. 1111, is now obtainable from Burroughs Wellcome & Co. It is known as the "Agla" Micrometer Syringe Apparatus and is suitable for the measurement of volumes from 0·5 c.c. (with an error of less than ± 0·1 per cent.) to those as small as 0·001 c.c. (with an error of less than 5 per cent.). In immunological work the instrument can measure volumes of the order of 0·01 c.c. with an error of less than ± 1 per cent.

The "Agla" Micrometer Syringe Apparatus enables a fine degree of accuracy to be attained in various delicate laboratory processes including the following: (1) Immunological titrations with very small quantities of serum. (2) The calibration of pipettes of small volume. For this purpose an ordinary fine hypodermic needle should be used and the required volume injected into the pipette by inserting the needle just inside the end of the capillary. (3) Micro-chemical titrations and micro-gas analyses, in which the instrument may be used as a burette.

Price in London, 55s. complete net. Further details may be obtained from Burroughs Wellcome & Co.

We have been informed that "Santonin" is now supplied in small quantities from ½ oz. upwards, suitable for the Tropics. To ensure its genuineness each package bears a label attractively printed in red and green containing the word "Santoninum" and the name of the exclusive official distributors, The Eastern and Russian Trading Co.

Original Communication.

AIRPLANE DUSTING IN THE CONTROL OF MALARIA MOSQUITOES.[1]

By W. V. King

AND

G. H. Bradley.

For the past three years experiments have been conducted by the United States Bureau of Entomology at Mound, Louisiana, on the use of airplanes in distributing larvicides over the breeding places of malaria-carrying mosquitoes. This work has been carried out with the co-operation of the Delta Laboratory, of the Bureau at Tallulah, Louisiana, and the Air Service of the United States Army. The planes used had been equipped for cotton dusting and were provided with metal dust hoppers installed in the rear cockpit, with an opening through the bottom of the fuselage for the release of the dust. The hoppers were designed to hold a load of 300 pounds of material and the rate of delivery could be varied by means of a sliding valve adjustment.

The possibilities of using planes for this purpose was suggested when it was found that Paris green applied as a dust was highly effective in destroying the larvæ of this particular kind of mosquito. These larvæ have the habit of feeding at the surface of the water and skim their food from the surface film. Paris green, although heavier than water, will float, due to the surface tension, long enough to be taken up by the larvæ along with their food. Since only a minute quantity is required to kill each larva

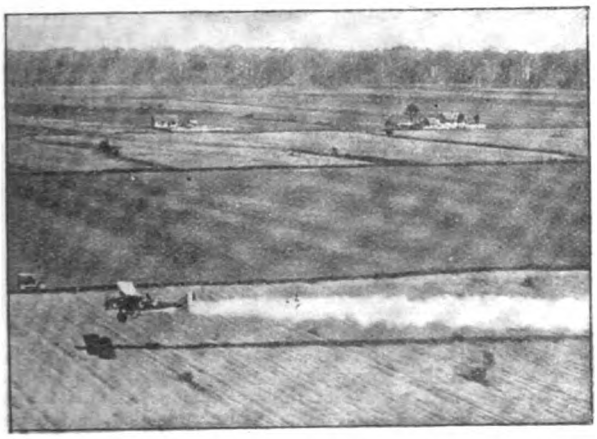

Fig. 1.—Dusting plane flown across open field to determine the spread of the Paris green and dust mixture under the most favourable conditions. Plane flying about 15 ft. above ground.

it is not necessary actually to poison the water, and for this reason fish are not injured and there is little or no danger from the drinking of treated water by domestic animals. Unfortunately, other species of mosquitoes which feed below the surface film are not affected, but in most of the malarious regions the other mosquito pests which are troublesome about the houses are not produced in the large swamp areas. Their breeding places are the water barrels and cisterns, ditches and small pools near

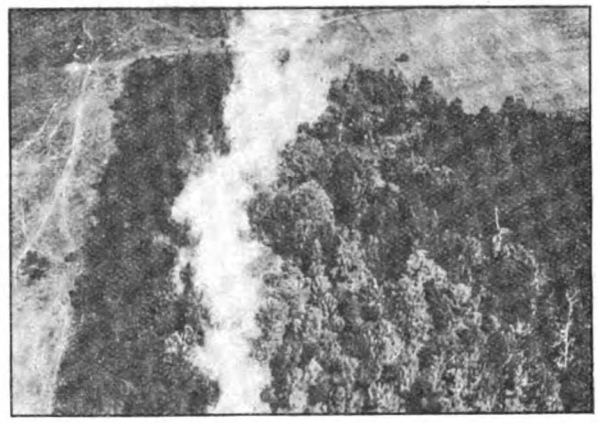

Fig. 2.—Dust cloud beginning to spread out among trees following a trip of the plane across Bienkiem Woods.

the dwellings which would not be subject to airplane treatment.

Because of the small quantity of Paris green required, an inert dust of some sort is used as a diluent and carrier. This is found to be quite necessary to secure thorough distribution without using an excessive amount of the poison. A variety of substances have been employed by ourselves and others, including ordinary road dust, sand, cork dust, calcium carbonate, diatomaceous earth, a mixture of lime and flour and an amorphous silicous dust known as Tripoli earth. These materials differ considerably in density and fineness of grain which affect distribution and especially the distance of drift. In most of our experiments we have used the Tripoli earth because of its availability and uniformity. It also had an advantage over the lighter materials in treating breeding places protected by trees, since its heavier weight caused it to settle more quickly.

The mixtures used for airplane distribution contained from 5 to 20 per cent. Paris green, 10 per cent. being the usual proportion. Under average conditions a ½ pound of Paris green per acre, or 5 pounds of the 10 per cent. mixture was taken as the basis for estimating the amount of dust to be used. This gave a leeway for a certain amount of wastage resulting from wind drift and adherence of the dust to the leaves of aquatic vegetation. Where the breeding places were protected by a heavy growth of brush and trees the amount of dust had to be considerably increased. On the other hand, where there was little vegetation above the water surface a much smaller quantity was required. The amount put

[1] Published by permission of the United States Bureau of Agriculture, given to Sir Ronald Ross.

out on a given area could be regulated by the opening of the hopper valve and by the distance between successive trips of the plane. Some substances fed out two or three times as fast as others, and this had to be taken into consideration in making the valve adjustments.

In effectively treating swamp areas careful attention had to be given to the drift of the dust cloud. In the early experiments the dusting was tried in the early morning when the air is usually still, but

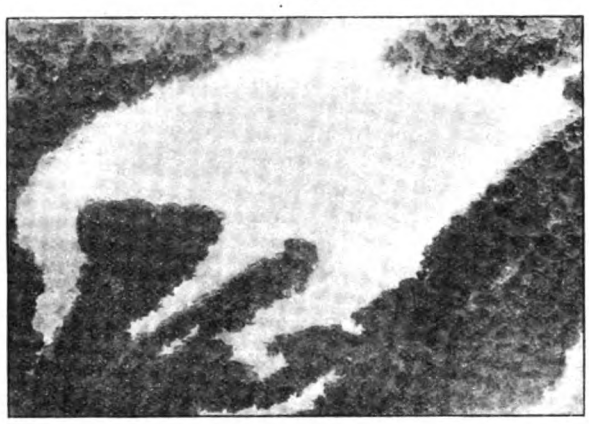

FIG. 3.—One of the larger swamp lakes.

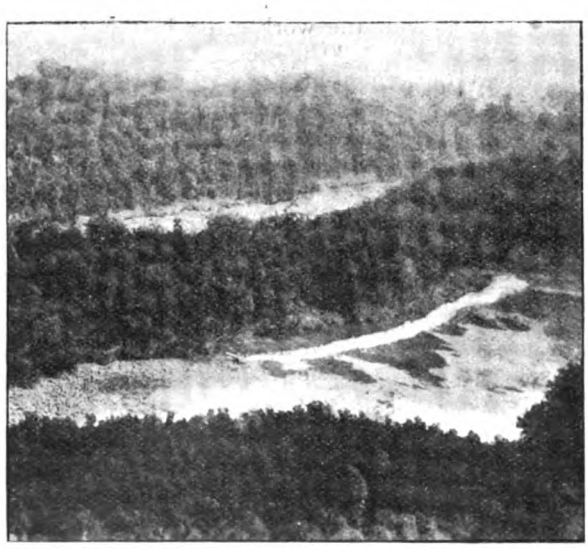

FIG. 4.—Dusting plane making flight over the centre of St. Via Lake, flying below the tops of the trees on each side.

the presence of dew on the leaves at this time of day proved to be a serious drawback, since it caught the dust particles and prevented their reaching the water surface. By the time the leaves become dry there is almost always more or less wind, but it was found that, with proper handling of the planes, a slight breeze was often of advantage in helping to distribute the dust. Occasionally, however, the wind at this time of day would be too strong for successful dusting and the operation would have to be postponed.

The shallow swamp lakes in this region consist usually of a central treeless area containing a growth of water-lilies and a variety of smaller aquatic vegetation favourable for mosquito breeding. Around the margins the water spreads out during a part of the season into a thick stand of brush and tall willow

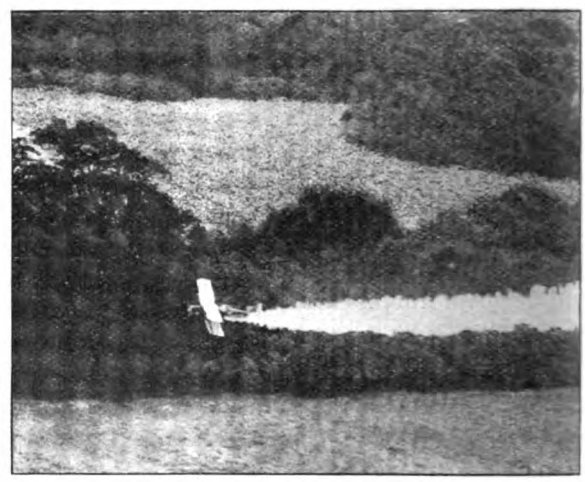

FIG. 5.—Dusting the marginal zone of Field Lake with the wind blowing towards the lake; the plane was flown outside of the tree line and the dust drifted into the breeding area.

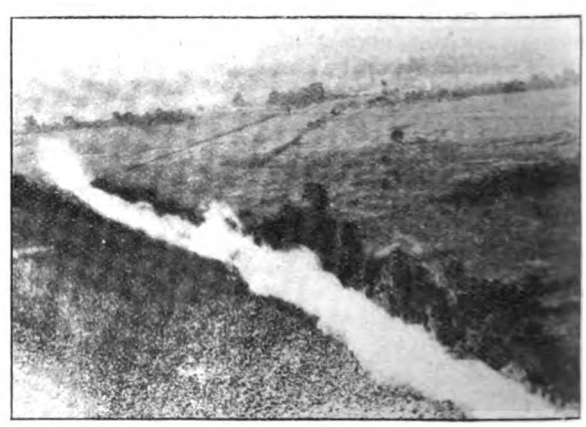

FIG. 6.—View of another dust cloud left in treating the marginal zone of Field Lake. In this case the plane was flown on the lake side of the trees, since the drift was towards the open field. The photograph also shows the heavy growth of water chinquapui, in a portion of the lake, completely obscuring the water surface.

trees. With a skilful pilot no especial difficulty was encountered in successfully treating the central portion, even when the lily growth was so thick as almost to obscure the water surface. The treatment of areas protected by brush and trees was a much more difficult proposition and the results under these conditions were

quite variable. When such breeding zones were comparatively narrow the application could be made by flying the planes on the windward side of the tree line and allowing the dust to drift in from the side. Where the area was larger it was necessary to fly directly over the tree tops, but even in such places the dust was found to penetrate the thick growth provided a sufficient quantity was used to offset the greatly increased wastage.

FIG 7.—Growth of water chinquapui in Blue Tuoret Lake at time of dusting test in 1924.

In work of this kind the greatest item of expense is, of course, the operation of the airplanes, but only approximate figures as to cost can be given at the present time. This matter has been discussed at length with representatives of the Huff, Daland

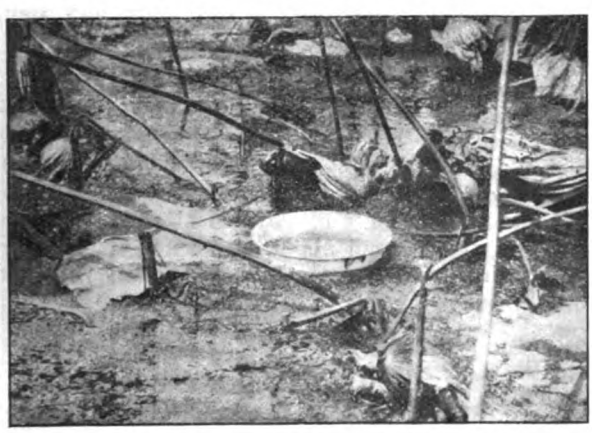

FIG. 8.—One of the pans containing larvæ and floating on the surface of the water, as used in the lake dusting experiments in 1924. The view also shows the water conditions encountered during these tests.

Aero Corporation, who undertook commercial cotton dusting against the boll weevil during the past season. The estimates arrived at have varied from fifty cents to about one dollar per acre, including the cost of poison. With a unit organized solely for lake dusting, a large acreage would have to be included to make the proposition feasible, and the cost would probably approximate the higher figure. However, if the work is carried out in conjunction with a cotton-dusting unit it is believed that the actual cost would be from fifty to sixty cents per acre on the average. This would provide an economical method of distribution were it necessary to make only a few applications. Unfortunately, Paris green remains effective on the water for only a very short time, and where mosquito breeding is continuous it is necessary to re-apply it every eight or nine days to prevent the emergence of adults. Consequently, the cost runs up rapidly over a period of several months.

As compared to any method of hand distribution, however, it is believed that, even under present conditions, the cost would be much in favour of airplanes on an area large enough to justify their use. Moreover, there are many swamp breeding places which it would be almost impossible to treat either from the ground or from boats.

During 1922, an experiment on the control of anopheles breeding areas by means of the hand distribution of diluted Paris green was undertaken by the Public Health Service, in the vicinity of Lake City, Florida. Figures published by Mr. T. B. Hayne, in charge of the work, showed that the cost of twelve applications to an area of approximately 475,000 square feet was $773 for labour and poison—a rate of about $5.90 per acre per application. Mr. Hayne estimated that, from the experience gained, the work could be repeated at a reduction of 20 to 30 per cent. in cost, and this would possibly represent the expense of such work under average conditions.

The use of temporary methods of malaria control such as poisoning and oiling are not, of course, employed except where drainage or other permanent measures cannot be undertaken at the time. The expense which would be justified in a control campaign in any community depends upon the size of the population affected and the severity of malaria infection. Even with these limitations, it is believed that a certain number of malarious locations are to be found where the distribution of Paris green by means of airplanes could be economically employed, and the opportunities would be materially increased by any reduction in the cost of airplane operation or by some improvement in the larvicide, so that the number of applications required would be reduced.

THE CAUSE OF THE HAIRLESSNESS OF MAN.

By H. N. RIDLEY.

AT the recent meeting of the British Association, Dr. Gunther read a paper on the above subject in which he suggested that the loss of hair on the body in man was due to the invention of fire, the nude varieties of man attacking and exterminating the hairy races with flaming brands which fired the body hair. This theory does not

appear to me at all a probable one, as I think that in a fight with fire between a nude man and a hairy one, the fire would injure the exposed skin more than one covered with hair, the hair acting to some extent as a protection. It is true that my large mias (orang outang) *Simia satyrus*, which lived so long in the London Zoological Gardens, rather objected to lighting his cigarettes with a match (though he knew well enough how to strike one and light the cigarette), as on some occasions the head of the match in striking it flew off into his beard and burnt him, but he would regularly light his own cigarette from a lighted one offered to him, and evidently knew how to handle fire in this way.

I would point out that Mousterian man, who was certainly hairy all over, knew how to make and handle fire, as Mousterian hearths have often been found, and we know that the much later Magdalenian man was also hairy and used fire.

A suggestion often made is that the loss of hair was caused by the wearing of clothes. This is easily disproved by the fact that the wild tribes who habitually go naked or formerly did so, such as the Sakais of the Malay Peninsula, and the Moi of Annam, are unusually hairless, much more so than the thickly-clad European, and that the head and pubes, the first portion of the body to be covered, are the most hairy parts.

I have two suggestions to make as to the cause of hairlessness of the body.

Some years ago, in my menagerie at Singapore, I had an adult female mias, and after I had her for some little time, I observed that after menstruation she lost almost entirely the hair from the abdomen and chest, quite suddenly. There was no signs of any skin disease to account for it, and in a short time the hair grew again. Some months later the same thing happened; I concluded that the reason of the hair-fall was to prevent the clotting of the hairs by milk should she breed. Unfortunately, I had no adult male, and some time after she died from the usual choleraic diarrhœa which is so fatal to these apes in captivity. The main nudity appeared from the chest to the lower part of the abdomen.

In the representation of the pregnant woman of Magdalenian age from Laugerie Basse, as figured in Sollas, "Ancient Hunters," p. 550, fig. 311, the hair is shown on the abdomen and outer side of the thighs and axilla only, not on the breast, in fact, mostly below the navel, very much as it appeared in the mias when on heat, though she was denuded rather lower. This denudation, so far as I have seen, does not occur in *Hylobates* nor in the lower monkeys, but in these the fur is short, close and dense, not so long and loose as it is in the mias. I have kept a number of *Hylobates* and they never bred in captivity. The fall of the hair in the breeding season in the female would not, of course, account for the denudation of the male, but it may have been a start in the permanent hairlessness of the body.

The second suggestion is that the loss of hair all over the body is due to injury caused by skin vermin, fleas or lice. It is not uncommon for oriental natives to shave the head in children, especially to get rid of lice. It is not difficult to keep free from such vermin when the hair is confined to the head and pubes, but it would be very difficult to do so if the body was entirely covered with hair. Now lice of themselves would not cause mortality among the tribe, but if one may conceive them as acting as propagators of disease of a dangerous character, it might be fatal to a tribe to be covered with them in long hair which could not be cleaned. We know now that both fleas and lice do carry deadly diseases, e.g., plague and typhus, trench fever and relapsing fever.

Is it not possible that when primitive man became herded together, living in close contact, some disease such as those mentioned might spread so as to exterminate all those who were thickly covered with hair? It must be noted that the common monkeys, and still more the anthropoid apes, live together in small detached families and not only would any such disease be less readily communicated from one to another, but in a small family of three or eight, the usual number in anthropoid and lower simians, it would be easy to keep each other clean. Monkeys of all kinds are peculiarly free of skin vermin owing to their habits of incessantly searching for them. Epidemic disease is the outcome of the crowding together of animals in communities. Primitive man, as far as is known, lived in small groups or families which had no constant or close communication with other groups, as the Sakais of the Malay Peninsula do at the present day; later they increased and formed communities. An invasion of a race bearing some disease-carrying parasite might infect and exterminate any hairy race, leaving only those who, being less furnished with hair on the body, could clean off the vermin.

I may point out that the era of the hairy Magdalenians was followed by the invasion of the neolithic Azilian race, who appear, from their introducing wheat, to have come from the East, and to have also brought with them the rat (R. Munro, "Palaeolithic Man," p. 251) so closely associated with the plague, and about this time all the hairy Palaeolithic men appear to have completely vanished.

REFUTATION OF STATEMENTS MADE BY PROFESSOR R. T. LEIPER, M.D., D.Sc., F.R.S., CONCERNING AFRICAN SCHISTOSOMES, "AMERICAN" GONGYLONEMAS, ZOO VERMIN AND ITALIAN CANCER HOUSES.

By Louis W. Sambon, M.D.

Lecturer in the London School of Hygiene and Tropical Medicine.

Not without regret, I have to reply to Professor R. T. Leiper, M.D., D.Sc., F.R.S., my colleague in the London School of Hygiene and Tropical Medicine, who has attacked my recent epidemio-

logical, helminthological and phytological researches on cancer.

The *Times*, in its issue of July 14, 1926, said: "One of the most interesting communications in the report (the *Annual Report for* 1925 *of the British Empire Cancer Campaign*, July, 1926) came from that brilliant investigator, Professor R. T. Leiper, whose work on Egyptian bilharziosis is still fresh in the scientific mind. Dr. Leiper, by a series of very careful studies, has disproved once more—and this time perhaps finally—of the theory of 'cancer houses,' even in its most scientific form. The theory was revived some time ago as the result of Fibiger of Copenhagen's discovery that cockroaches played the part of host to a worm capable of causing cancer in rats. The cockroach as a carrier of agents of human cancer has been acquitted by Dr. Leiper."

The report mentioned in the *Times* is entitled "Some Observations and Reflections on Recent Attempts to Implicate the Gongylonema Worm in the Causation of Cancer in Man," by Professor R. T. Leiper, M.D., D.Sc., F.R.S.

I will deal first with some of the facts concerning Egyptian bilharziosis.

Now, it happens that, no less than seven years before Professor Leiper, I demonstrated clearly that there were, in Egypt, two different species of blood-flukes affecting man: (1) *Schistosoma hæmatobium* Bilharz, 1851, affecting the urogenital system and giving rise to endemic hæmaturia; (2) *Schistosoma mansoni* Sambon, 1907, affecting the large bowel and producing dysenteric symptoms. The most striking morphological difference between these two species, the one most easily seen and of diagnostic importance, lies in the armature of their ova: the egg of *Schistosoma hæmatobium* being provided with a terminal spike, whilst that of *Schistosoma mansoni* bears a lateral one. Lack of material and the bad preservation of the two female specimens I had the opportunity of examining, prevented me from indicating any morphological differences in the build of the adult worms, but I brought forward a wealth of evidence to show that, though sometimes associated, in overlapping distributional areas, the two species differed markedly in their geographical range and topographical distribution. Further, notwithstanding the failure of numerous investigators (Cobbold, Sonsino, Lortet, Vialeton, Looss) to find any molluscan, arthropod, or piscine intermediate host, and rejecting the opinion of Professor Looss, which denied the necessity of any intermediary (as previously surmised by Professor Grassi in the case of *Schistosoma bovis*), I pointed out that these schistosomes, like other digenetic trematodes, necessarily must have gasteropod intermediate hosts. These statements were by no means negligible guesses, but inevitable conclusions derived from well-ascertained facts, from suitable analogies and from a correct interpretation of extant knowledge. Indeed, eminent helminthologists, such as Professors Blanchard, Railliet and Brumpt in France; Stiles, Ward and Lutz in America; Drs. Low, Chalmers and Castellani in this country, at once accepted my views.

Professor Looss, on the other hand, opposed me bitterly and it was on the occasion of his second diatribe that Professor Leiper, taking advantage of the very first number of a journal issued by our school (see *The Journal of the London School of Tropical Medicine*, Vol. 1, Part 1, December, 1911), wrote these memorable words:—

"In a highly interesting communication Prof. Looss brings to a close, it is to be hoped, the recent controversy upon the significance of the 'lateral spine' sometimes met with in eggs from cases of African bilharziasis. He conclusively demonstrates that Dr. Sambon's 'species' and his own 'hypothesis' are untenable."

What followed?

Keen Japanese scientific workers (Miyagawa, Miyairi, Suzuki, Ogata), between 1910-14, made a thorough investigation of their own particular form of schistosomiasis—a disease long known in Nippon under the name of "Katayama disease" and due to the parasitism of *Schistosoma japonicum* Katsurada, 1904. They proved that, as I had suggested for the African schistosomes, the Oriental blood-fluke has a gasteropod intermediate host—the Katayama snail *Katayama* (= *Hypsobia*) *nosophora* Robson 1914, and that its cercaria—a fork-tailed larva—dropping its bifid swimming appendage and drilling its way through skin or mucous membrane, can successfully infest man, dog, cat, ox, horse, hog or field-mouse.

In 1914, Professor Leiper went to Japan, where he had the opportunity of studying and verifying the work of the Japanese investigators and learning their ingenious methods. Then he proceeded to Egypt and there, of course, had no difficulty in confirming my statements of 1907, which he had so "hopefully" repudiated in 1911. Professor Leiper was forced to recognize that, in the land of the Sphinx, there are two species of schistosome affecting man, each producing a differently formed egg and that their miracidia do penetrate fresh-water snails, each species choosing, as I had predicted, a particular kind of gasteropod: *Planorbis boissyi*, in the case of my new species *Schistosoma mansoni*, and *Isidora truncata* (olim *Bullinus contortus*), in that of the old species *Schistosoma hæmatobium* described by Bilharz in 1851.

In his lecture on bilharziosis, delivered at the Royal Society of Medicine in 1916, Professor Leiper said: "Manson had always maintained that the lateral-spined egg, having a different geographical distribution (*sic*) and producing normally dysenteric symptoms only, was the product of a different species. This view was strongly supported by Sambon, who maintained with great skill a vigorous polemic against Looss's position. Sambon was forced to regard the adult parasites as practically indistinguishable in the absence of reliable details."

These acknowledgments are neither full nor correct. Manson had *not* always maintained that the schistosome producing a lateral-spined egg was

specifically different from the one producing a terminal-spined egg. Indeed, in 1902, when I examined one of his patients helminthologically and found lateral-spined schistosome eggs instead of necator or ankylostoma eggs, as suspected, in an anæmic Englishman from the West Indies, invalided home by Dr. Branch, of Antigua, we discussed the case and I insisted on regarding the lateral-spined egg as evidence of a separate species, yet Manson published this case in the JOURNAL OF TROPICAL MEDICINE (December 15, 1902) as one of *Bilharzia hæmatobia* and said: "In this case, as often happens in bilharzia ova from the alimentary canal, the spine is placed laterally." In this article on the Antigua case there is no allusion whatever to a separate species which, according to Professor Leiper, "Manson had always maintained," but ample evidence to show that then he had not accepted my view of the matter.[1] At that time I was helping Manson to prepare the third edition of his "Manual of Tropical Diseases," and, forcibly struck by this sufferer of intestinal schistosomiasis who had been nowhere else abroad than in the Caribbee Islands, where endemic hæmaturia is unknown, I continued to discuss the subject and urged Manson to suggest the probability at least of two different species. Manson then wrote: "Possibly there are two species of bilharzia, one with lateral-spined ova, depositing its eggs in the rectum only; the other haunting bladder or rectum indifferently." In his Lane Lectures, published two years later (1905), still diffident, he says: "It may be that in this difference in the position of the spine in vesical and rectal bilharziosis we have an indication of difference of species." Finally, after I had proposed definitely myself the form with lateral-spined egg as a separate species (*Proceedings of the Zoological Society*, March 9, 1907), Manson fully recognized the duality of species and in the fourth edition of his book (August, 1907) wrote: "This case (Antigua case, 1903) led me to think that probably the lateral-spined ova indicated a distinct species of schistosomum, and I suggested this in a previous edition of this manual and elsewhere (Lane Lectures)." Further, he says: "Sambon, having had the opportunity of comparing specimens of the type characterized by lateral-spined ova with *Schistosoma hæmatobium* and other schistosomidæ, and taking into consideration its peculiar geographical distribution and distinct pathogeny, proposed that it should be ranked as a distinct species, and paid me the compliment of naming it *Schistosoma mansoni* in recognition of my suggestion." In the preface to his manual Manson says: "I desire especially to acknowledge my obligation to Dr. L. Sambon for much assistance in bringing the zoological information and nomenclature up to date." Professor Leiper must have known all this, but, doubtless, he had forgotten.

Now let us consider Professor Leiper's attack on my cancer work.

After the publication of my Paris lecture at the Institut Pasteur, on the "Epidemiology of Cancer" (JOURNAL OF TROPICAL MEDICINE, February 2, 1925), Professor Leiper took up the study of the part helminths might play in the perplexing labyrinth of cancer ætiology and commenced, as I had done, by taking up the thread-worm Gongylonema. Indeed, one day, last year, at the London School of Tropical Medicine, he told me that he was going to Villa Lagarina (one of the Tridentine villages I had chosen for research work on account of the peculiar limitation of cancer to one section only—practically one street—during the last half century). "Why not join us in our work?" I asked, though, at the time, I thought he was not serious.

Whilst in Italy, I learnt that Professor Leiper and Dr. T. W. M. Cameron, M.R.C.V.S., were in Milan collecting specimens of gongylonema in the municipal slaughter-house. Later, I read that Professor Leiper had obtained a grant for this purpose from the British Empire Cancer Campaign.

After my return home, The British Empire Cancer Campaign, which financed our expedition, informed the Committee of the Tropical Disease Prevention Association, under whose auspices I had been working, that Professor Leiper had been asked to examine our helminthological material. Although this request seemed unusual—that Dr. Baylis, helminthologist in the British Museum, and myself, lecturer in the London School of Tropical Medicine, should place our material and unpublished reports in the hands of an investigator who, to their knowledge, was working on the same subject and who had followed us to the same country for the collection of his material, yet, in accordance with our agreement and fully relying on the fairness of the British Empire Cancer Campaign, no demur was made.

Soon after, at a meeting of the Zoological Society of London, held on June 1, 1926, under the presidency of Sir John Bland-Sutton, Bart., F.R.C.S., Professor Leiper read a paper on "Some Parasites of Rats in the Zoological Society's Gardens." Under cover of this title, Professor Leiper launched an attack on the results and views of Dr. Baylis and myself, notwithstanding that not only our published but our unpublished reports also had been placed in his hands.

Sir John Bland-Sutton, vice-chairman of the British Empire Cancer Campaign, supported the speaker and stated that one should be grateful to any person who came forward to test unfounded theories, especially in the case of cancer, and thus prevent the public being misled. These words were widely reported in the lay press. Thus the *Westminster Gazette* (June 2, 1926) wrote that Professor Leiper, of the School of Tropical Medicine

[1] An earlier West Indian case from Martinique had been described by Professor Maurice Letulle as presenting both lateral and terminal-spined eggs, and was so considered by pathologists and helminthologists until I pointed out that the short terminal-spined eggs in Letulle's sections were microtome artefacts. "If a lateral-spined egg is sectioned obliquely at the base of the spine and in a line with the axis of the spine, it is manifest that the resulting figure would be an oval with a spine at one end of the long axis."

had "exploded Dr. Sambon's theory" and that he was "preparing a damning report."

This report was considered by the Grand Council of the British Empire Cancer Campaign at their meeting held at the House of Lords, on July 12, 1926; it formed part of the Campaign's annual report and was submitted to the press.

Finally, it is necessary to state that, whilst the Grand Council of the British Empire Cancer Campaign formally approved the publication of Professor Leiper's report, already printed and incorporated in their annual report for 1925, they again delayed the publication of my report, notwithstanding Leiper's attack and the fact that it had been over six months in their hands. They referred it to yet another committee!

At length, on July 20, 1926, the secretary of the Campaign wrote that his committee did not feel justified in objecting to our association communicating to some scientific journal the results of our investigations in Italy, but hoped that, having read and considered Professor Leiper's report, which was cordially endorsed by the Campaign, our association would give consideration to the views contained in that report.

The following is a careful consideration of Professor Leiper's "Observations and Reflections" (published in the *Annual Report of the British Empire Cancer Campaign*, 1926) on my recent cancer investigations.

Professor Leiper begins his paper with a quotation which he seems to have borrowed from my Paris lecture. I had quoted words of the late Dr. E. F. Bashford, Director of the Imperial Cancer Research Fund, who, anathematizing "cancer houses," had said: "Let us hope that the danger of cancer houses will cease to alarm the public and divert the energies of investigators from *fruitful* lines of inquiry." Professor Leiper, in his accurate manner, has substituted the word "futile" for "fruitful."

This misquotation is followed by a chaplet of short sentences culled from my paper and strung on a twist of extraneous words, a method purporting to present the opponent's views in his very words, but often misrepresenting them through omission, transposition or interpolation. I do not suggest that such is wilfully the case in the present instance, but I do wish to deprecate this objectionable method.

At the end of his quotations, Professor Leiper remarks that "Dr. Sambon has revived in a definite form the old cancer house theory." This is quite correct, but not so what follows.

I never "assumed," as Professor Leiper gratuitously asserts, "that in the old houses—especially in cancer houses—rats harbouring *Gongylonema neoplasticum* 'occur,'" nor did I state, as he again advances, "that man 'can' be infected with this gongylonema, which hitherto has been found only in the rat."

Certainly, and for good reason, did I think that it would be desirable to find out whether rats or mice infested with *Gongylonema neoplasticum* did occur in or near houses where cases of buccal, œsophageal or gastric cancer had occurred, and I did think, and still do think, that the rat gongylonema may be capable of infecting man; since experimentally it is easily transmitted to the most diverse animals such as mice, guinea-pigs, rabbits and sheep. So far, however, as stated in my report, I have not found rats infested with *Gongylonema neoplasticum* in any of the Italian villages which I have had the opportunity of visiting, and as to the form of gongylonema hitherto found in man, I stated that this in Italy, as in the United States of America, was probably the one believed to be peculiar to the pig and called *Gongylonema pulchrum*.

This brings us to the section entitled Discussion. Here Professor Leiper states that, from a study of my "published" reports and of the subsidiary publications by members of the staff of the British Museum who accompanied me, he is forced to the conclusion that:—

(1) No evidence is forthcoming that rats in Italy are infested at all with *Gongylonema neoplasticum*, which he declares is a parasite of tropical America and the West Indies.

(2) The natural intermediary host of *Gongylonema neoplasticum*, the American cockroach (*Periplaneta americana*), does not appear to have become established in Italy.

(3) No case of *Gongylonema neoplasticum* was found in man.

Conclusion 1 is perfectly true, indeed it is on the strength of our own negative evidence that Professor Leiper states that we did not find *Gongylonema neoplasticum* in any of the rats we were able to capture at Villa Lagarina and other Trentino villages. But the rats examined by us were few in number and neither Baylis nor I would accept this as proof that *Gongylonema neoplasticum* does not occur in Italy.

At the foot of conclusion 1 Professor Leiper makes a very definite statement, he says:

"Here it may be remarked that *Gongylonema neoplasticum* is a parasite of tropical America and the West Indies, and has never been found in Europe save in warehouses or other buildings connected with the importation of sugar or other commodities arriving by ship from these regions."

Considering the cosmopolitanism of rats and their notoriety as wanderers, together with the same cosmopolitan habits of the "ship cockroach" (*Periplaneta americana*), recalling also that other Blattidæ (*Blatta orientalis* and *Blattella germanica*) and certain beetles such as meal beetles (*Tenebrio molitor* and *Tenebrio obscurus*) are able to foster the larval stages of *Gongylonema neoplasticum* I fail to understand Professor Leiper's rashness. Indeed, had I not read it in the "Annual Report of the British Empire Cancer Campaign," I should not have believed that Professor Leiper could have devised, written and published such a statement.

In the first place *Gongylonema neoplasticum* (or forms indistinguishable from it) has been described

from various parts of Europe and Asia. Thus Yokogawa (1925) has described what appears to be the same form from Formosa, under the name *Gongylonema orientale*, and states that there, as in Europe, it gives rise to cancroid growths in the stomach of rats. In 1924, Dr. R. E. Schulz described yet another form from mice in South Russia and Turkestan. Unable to differentiate this gongylonema from *Gongylonema neoplasticum* and, fully aware of the fact that great variability is characteristic of this genus, Schulz jokingly suggests the provisional name *problematicum* and states that his presumptive species cannot be distinguished from *Gongylonema neoplasticum* and *Gongylonema musculi*.

The very first species of gongylonema described was a mouse gongylonema collected in Austria by Rudolphi, in 1819, and named by him *Filaria musculi*. Rudolphi, as I have shown, confounded two different parasites of the mouse, one the gongylonema found "*Circa ventriculum*," the other, *Hepaticola hepatica*, found "*in hepate*." In 1845, Dujardin had the opportunity of examining a female specimen of Rudolphi's *Filaria musculi*, sent from Vienna to the Paris Museum; it measured 21·6 mm. in length by 0·154 mm. in thickness. It presented two lateral membranous alæ in the anterior portion and its ova measured 45 microns in length, by half that size in width. He thought these characters suggested a *Spiroptera*. In 1857, R. Molin examined Rudolphi's *Filaria musculi*, established for it the genus *Gongylonema* and called it *Gongylonema minimum*.

Both Baylis and I have described a female specimen from the house-mouse which we could not distinguish from *Gongylonema neoplasticum*; it was collected with other specimens by Dr. Wassink in an Amsterdam sugar refinery said to be free from rats, but no doubt infested with cockroaches. Wassink's specimens showed that *Gongylonema neoplasticum*, under natural conditions, can develop perfectly well in the house-mouse.

In 1914, Seurat described under the name of *Gongylonema brevispiculum* a gongylonema found in the dwarf jerboa (*Dipodillus campestris*) in Algeria which Maurice C. Hall believes to be identical with *Gongylonema neoplasticum*.

Need I say that *Gongylonema neoplasticum* has been found in several northern countries such as Holland and Denmark and that it was in Copenhagen that Professor J. Fibiger first noticed its association with gastric carcinoma in rats?

The above facts, all published and accessible to the helminthologist, are incompatible with the statement made by Professor Leiper that *Gongylonema neoplasticum* is a parasite of the neotropical region and has never been found in Europe, save in warehouses or other buildings connected with the importation of sugar or other commodities arriving by ship from these regions.

This statement was made by Professor Leiper at the very time when, while controlling our researches, he accidentally discovered *Gongylonema neoplasticum* in England, in the rats and cockroaches of the London Zoological Gardens, not in a sugar refinery, nor in anything connected with sugar, but in the reptile-house, where they have existed and swarmed unmolested for at least half a century, because, in 1868, writing in *Science Gossip*, "H.C.R." says that *Periplaneta americana* occurs in warehouses near the Thames, in Red Lion and Bloomsbury Squares, and the Zoological Gardens, Regent's Park. Professor Leiper, in the paper he read at the Zoological Society of London on May 11, 1926, stated that he had found malignant neoplasms associated with *Gongylonema neoplasticum* in the few Zoo rats he had examined, and this ominous statement, so contrary to the views he was expressing, was reported in the lay press. But with this I shall deal elsewhere.

Nor is this all. Every zoologist knows that true rats and mice (indeed, the whole of the murine sub-family) belong to the Old World and, probably, the same may be said of the so-called American cockroach. Walsh doubts the American origin of *Periplaneta americana* and suspects its importation from Asia.[1] "This species," he says, "does not appear to hail from South America and has followed the trade routes over nearly all the world." Is it conceivable then that, as Professor Leiper naively

[1] Because of the absurdity of Professor Leiper's mistake, I have thought it necessary to corroborate my own evidence by authoritative statement. Thus, with regard to the distribution of rats and mice, I am able to quote Mr. Martin A. C. Hinton, a distinguished mammalogist in the British Museum, who writes: "The subfamily Murinæ is without doubt of Old World origin. South-eastern Asia is probably to be regarded as the original home of the group. From this centre the Murinæ have spread outwards during Tertiary times, so that the natural range of the subfamily now extends throughout the whole of Asia, and includes the Australian region, Europe and Africa. It arrived in Eastern Africa after the separation of Madagascar, and in North-eastern Asia and North-western Europe after the destruction of the bridges between the Old and New Worlds. In Madagascar and the American continent therefore no trace of any living or fossil member of the subfamily, indigenous to those countries, has ever been discovered. In quite recent times, however, rats (*Rattus rattus* and *Rattus norvegicus*) and the house mouse (*Mus musculus*) have been conveyed by human commerce to all parts of the world. The three species in question are undoubtedly of Asiatic origin, although they now enjoy a secondary cosmopolitan distribution."

Concerning the cockroaches, I consulted Mr. B. P. Uvarov, of the Imperial Bureau of Entomology, and he kindly wrote: "R. Shelford (Genera Insectorum, 109 fasc., *Orthoptera, Blattidae*, subfam. *Blattinae*; 1910; p. 17) refers to the genus *Periplaneta* 37 species (discounting 3 doubtful species). Of this number only *three* are not known in the Old World, the rest being either purely Old World species, or species of cosmopolitan distribution (like *Periplaneta americana, australasiæ* and *truncata*). Two of the New World species (viz., *fuliginosa* Serv. and *insignis* Serv.) have not been sufficiently well studied to be certain that they really belong to this genus, and the only species of *Periplaneta* known from South America and not recorded from the Old World is *Periplaneta brunnea* Burm. This evidence seems to indicate that the genus *Periplaneta* is of Old World origin."

states, *Gongylonema neoplasticum* could be a New World parasite peculiar to Old World hosts and that it is confined to America and the West Indies, while the numerous scientists who have found it and described it from the most sundered parts of Europe and Asia, wherever rats and cockroaches do congregate must all have been mistaken? So remarkable a phenomenon in parasitology has hitherto not been imagined by the multitude of lesser helminthologists!

Not only is the rat Gongylonema an Old World parasite, but the genus Gongylonema itself is certainly of Old World origin. Gongylonema occurs in domestic swine and cattle on the American continent, but, so far, it has never been found in any wild American animal.[1] True swine (*Suidæ*) are confined to the Old World and domestic pigs were not introduced into America before the seventeenth century. Bovines are undoubtedly of Old World origin, the bison and its extinct relatives being comparatively recent immigrants into the New World, which they reached by way of Behring Strait, formerly an isthmus.

But are we quite sure that *Gongylonema neoplasticum* is a good species? So far, the only character by which it can be distinguished from the gongylonema of cattle, pigs and man is the smaller relative size of the left spicule, and that feature, like every other character in *Gongylonema*, is an exceedingly variable one.

With regard to conclusion 2, I believe it can be assumed that *Periplaneta americana* is unknown in the Trentino, but on the other hand *Blatta orientalis* and *Blattella germanica* are exceedingly common, while both are known to be able to foster the larval stages of *Gongylonema neoplasticum* and *Gongylonema scutatum*.

The answer to conclusion 3 is that we had practically no opportunity of looking for gongylonema in man. If we consider *Gongylonema neoplasticum* a separate and good species and not a variety or mere synonym of *Gongylonema pulchrum*, then, as it was not found in the local rats and cockroaches examined, it was unlikely to be found in man. But as the name we give a parasite, whether we consider it species, variety or host-race, of much importance? What I think important is the fact that I was able to establish the presence of *Gongylonema* in Europe as an occasional parasite of man, first by exhuming it out of literature, where it lay buried under the name of *Filaria labialis* Pane 1864, then tracking a case described by Professor Alessandrini twelve years ago (1914), but which had escaped the notice of helminthologists and is not mentioned in that thesaurus of helminthological information which is the American index-catalogue of medical and veterinary zoology. I found this patient, accompanied her, with her physician and Dr. Pan, to the various places where she had resided, and determined the locality where infection had occurred. Finally, through Professor Alessandrini's courtesy, Baylis and I were able to see, examine and compare with other specimens the worms extracted from beneath the girl's tongue.

Professor Leiper's three conclusions are followed by a summary of some of the parasitological work carried out in Italy by Dr. Baylis with the assistance of Dr. Pan and my daughter, Miss Juliette Sambon. Then follows the misleading suggestion that I ascribed to *Gongylonema* infestation the occurrence of "cancer houses" and "cancer villages" in Italy, and Professor Leiper says: "There has been complete failure to correlate gastric carcinoma with the occurrence of gongylonema in rats and vermin in the so-called 'cancer houses' and 'cancer villages' in Italy."

Continuing in the same manner, he says: "This occurrence of gongylonema in stock in the neighbourhood of the so-called 'cancer villages' has now to be considered in its possible relationship to human cancer in these villages."

He mentions the village of Villa Lagarina and implies that Dr. Ciurcentaler, by saying: "I have discovered in Villa Lagarina important epidemiological facts which confirm in every way your theory," alludes to gongylonema, while, instead, it refers to my infection theory generally. Then he says:—

"The rats, house vermin and the parasites of stock in this village were very intensively studied. The only cockroaches found there were identified by the British Museum as *Blatta orientalis*.

"These results seem of themselves to provide sufficient evidence that gongylonema cannot be the cause or explanation of the alleged frequency of gastric carcinoma in Villa Lagarina. In this village the cases are limited practically to the houses in a single street. The only cockroach found in the village is *Blatta orientalis*, which, as stated by them, cannot be experimentally infected with the cattle gongylonema. The other species of cockroaches —*Periplaneta americana* and *Blattella germanica*—which can act as carriers of the rat and cattle gongylonema respectively, were not found there. Finally, although the cattle gongylonema was experimentally transmitted by them to laboratory-bred rats by feeding these on dung-beetles, no naturally infected rats were found in the village, nor were dung-beetles found in the houses or cow-sheds. There is no reason to suppose that rats which might have become infected with *Gongylonema pulchrum* in the fields would return only to the so-called 'cancer houses.' Even if they did so, no effective intermediary has been found awaiting them there to transmit the infective stage to man."

[1] In his work on "Nematode Parasites of Mammals of the Orders Rodentia, Lagomorpha, and Hyracoidea," Maurice C. Hall lists a *Gongylonema* (?) *species* Hall, 1916, found in the stomach of *Castor fiber* from the United States (? Michigan), but, as he states, this is merely "a tentative assignment," based on nothing more than the following words: "In the stomach of the beaver I have found a very fine filamentous worm 40″ in length, species unknown," (in a footnote to Morgan's work on the American beaver, 1868). Hall says: "The fact that this worm was very fine, 3½ in. long, and located in the stomach, suggests that it might be a species of Gongylonema." The distinguished American helminthologist certainly beats me in boldness, yet I fear he is wrong. *Hepaticola gastrica* Baylis 1926, not known when he wrote, is likely to be a better guess. In any case, the beaver, though widely distributed throughout the Holarctic region, had its origin in the Old World. It inhabited the English fens, from Pleistocene times, and was found as late as the sixteenth century in Wales.

Twice Professor Leiper tells us that "the only cockroaches found in Villa Lagarina were identified by the British Museum as *Blatta orientalis*." Yet, I had stated quite clearly in my report that "Notwithstanding the absence of gongylonema in the mice and rats we were able to capture in Villa Lagarina, we carefully examined cockroaches (*Blatta orientalis* and *Blattella germanica*), cellar-beetles (*Blaps lethifera*) and meal-worm beetles (*Tenebrio molitor* and *Tenebrio obscurus*), but invariably with negative results." Our entomological material was determined on the spot, or after our return, by Mr. K. G. Blair, of the British Museum, who was a member of the commission. The various domestic species of cockroaches, however, are not difficult to identify. One may need a specialist to determine fleas, but lice and other animals fond of man and his ways, even poets, such as Quintus Serenus and Robert Burns, can diagnose and describe.

With regard to my alleged attempt to "correlate the presence of gongylonema in man with cancer houses and cancer villages in Italy," I need but quote verbatim the statements made in my report.

After mentioning striking peculiarities in the topographical distribution and visceral location of cancer, I said:—

"They forcibly suggested an infection of specific nature, probably dependent for its transmission and development on intermediary agencies with like distribution and, if animate, with correlative bionomics. Therefore I proposed making in Villa Lagarina and other suitable villages a comparative study of the flora and fauna of houses with and without cancer cases in order to find out whether household pests such as fungi, cockroaches, cellar-beetles, meal-worms, bed-bugs, rats or mice were present, and whether they played any part in the incidence of the disease, or if any parasites, fostered by house vermin, might be concerned."

At the beginning of my parasitological considerations, I said:—

"Because in previous reports I had discussed at some length the part played by certain helminths (*Cysticercus fasciolaris, Opisthorchis felineus, Schistosoma hæmatobium, Oxyuris vermicularis, Trichinella spiralis, Gongylonema neoplasticum*, &c.) in the ætiology of tumours, it was suggested that, in the course of my epidemiological investigations in the Trentino, I should endeavour to ascertain whether any parasitic worm, fostered by house-vermin during its earlier stages, might not later become a factor in the production of cancer in man, or in domestic animals harbouring its adult forms."

With regard to gongylonema, I said:—

"As stated in previous reports, researches made by Dr. Baylis and myself in Italy during the autumn of 1924 had elicited the fact that gongylonema was present in the cattle, sheep, goats and hogs of the provinces of Bologna, Ravenna and Trento, though with greatly varying prevalence in the different animals examined and in the different districts visited.

"We did not go to Villa Lagarina solely to study gongylonema; our object was to endeavour to find out, if possible, why cancer showed peculiar limitations in its topographical distribution, why it affected certain houses or groups of houses, leaving others in the vicinity untouched.

"Suspicion having fallen, since long ago, on rats, mice, blackbeetles, churchyard-beetles and other vermin infesting old buildings, it was our purpose thoroughly to investigate these house pests and anything else that might explain well-ascertained restrictions of the disease to particular streets, blocks of houses, or isolated cottages.

"As stated, we found no gongylonema in the rats, mice, cockroaches, cellar-beetles and meal-worm beetles in Villa Lagarina, but the number of mice and rats examined was, unfortunately, very meagre. On the other hand, we found gongylonema rampant in the local cattle and dung-beetles. Swine we were unable to examine, because none were being slaughtered at the time, but, from our researches in neighbouring localities, we know that they do harbour this nematode parasite when pastured.

"The absence or great rarity of gongylonema in household vermin, its restriction to cattle and dung-chafers, whilst necessarily minimizing the importance of any part it might play in the incidence of cancer in Villa Lagarina did not exclude it. Indeed, if Dr. Baylis is right in assuming identity between swine and cattle gongylonemas, the local cattle harboured that very form (*Gongylonema pulchrum*) which has been reported from man both in Europe and America."

In a previous report (JOURNAL OF TROPICAL MEDICINE, February 2, 1925), I said:—

"For obvious reasons, I have spoken at length of *Gongylonema* and of its intermediary hosts, but I should not like it to be inferred that I give exclusive importance to it, for, in truth, it is only one of several animal parasites which may be concerned in the complex ætiology of cancer."

Finally, I must point out that in all my reports I have stated most emphatically that "whatever be the rôle of parasitic worms, the actual essential cause of cancer is some ubiquitous micro-organism, probably a filter-passer, as the researches of Rous and his fellow-workers seem to indicate." Dr. Gye's recent investigations have brought further confirmation of this view.

That Professor Leiper, in the face of these explicit statements, could report that I endeavoured to explain the cause or frequency of gastric carcinoma and the occurrence of "cancer houses" by gongylonema infestation is difficult to understand.

"We agree with Dr. Baylis," says Professor Leiper, "that these domestic animals (cattle and swine) will have to be considered as important reservoirs of the parasite found in man, for it is evident that gongylonema in man is the species which normally occurs in pigs, but we cannot accept his further conclusion that 'if Dr. Sambon's theory receives confirmation,' then they have to be considered 'as factors in the spread of carcinoma,' for none of the gongylonemas found in domestic stock are associated with the occurrence of cancer in these animals, nor has cancer been observed in any of the cases in which gongylonema has hitherto been recorded in man."

The fact that hitherto cancer had not been found associated with gongylonema in man is in no way surprising since, up to date, only six cases of infestation with gongylonema have been reported, all in young people. The worms, usually immature forms, were discovered in these cases, because they had wandered into the lining of the buccal cavity. Hitherto, gongylonema has not been looked for in the œsophagus post mortem, this organ being very seldom examined.

With regard to cattle and pigs, it must be observed that these food-animals are slaughtered when comparatively young and that gongylonema infesta-

is usually overlooked. Thus when Dr. Baylis and I visited Italy (Trentino, Romagna, Bologna) in 1924, we found that, though exceedingly common in sheep, oxen and swine, gongylonema had escaped detection by the abattoir veterinarians.

Professor Leiper conveniently overlooks my statement that "Examination of the gullet of cattle infected with gongylonema often revealed papillomatous growths in the form of nodular, villous or coralline prominences, but I have no reason to suppose that they were necessarily dependent on the presence of the worm. I have seen identical proliferations of the papillæ and their overlying epithelium in gullets of cattle without gongylonema and in animals bred in districts apparently free from this parasite."

I could have made much of these papillomatous growths, which closely resemble the precancerous excrescences observed in tarred mice, and no doubt I should have done, but purposely made only passing mention of them. Likewise, whilst I considered that Baylis' views as to the identity of the cattle and swine gongylonemas and the extremely close relationship between these and the rat gongylonema were based on sound morphological and biological grounds, I still treated them as separate host-races lest I might too readily interpret evidence in favour of my own views.

Professor Leiper's contention that, of the very doubtfully distinct species *Gongylonema pulchrum*, *Gongylonema scutatum*, *Gongylonema ransomi*, *Gongylonema subtile*, *Gongylonema hominis*, *Gongylonema neoplasticum*, *Gongylonema orientale*, *Gongylonema musculi*, *Gongylonema brevispiculum* and *Gongylonema problematicum*, the only one capable of giving rise to cancer is *Gongylonema neoplasticum*, as if the production of malignant tumours were the true specific character in the absence of any other, is a strange mistake. A new species of *Hepaticola*, found by us in the stomach of Italian rats and described by Dr. Baylis, also gives rise to malignant neoplasms, just like many other nematodes, cestodes and trematodes, provided that the essential specific cause of cancer be also present.

The most remarkable part of Professor Leiper's paper is the section in which he deals with his own experimental work. He begins by telling us how he obtained specimens of gongylonema from cattle and sheep in the Milanese slaughter-houses, and informs us that "*The eggs from these worms* were brought back to England for experimental work." But he does not mention the type of egg-case or hatching-egg package used!

"The object of the experiment," he says, "was to establish, or disprove, the suggestion put forward by Baylis that the species of gongylonema found in stock in Italy was probably identical with that peculiar to the rat, the morphological differences being due to the influence of the host."

Dr. Baylis, as a systematist, being unable to find any definite morphological peculiarities, save very variable differences in size, between several of the hitherto proposed species of *Gongylonema*, was necessarily obliged, in a revision of the group, to reduce the number of previously accepted species. He recognized, however, the influence of particular hosts and the formation of adaptive host-races which, *after long restriction to the same host-species* may, and often do, develop changes sufficiently marked to sanction the establishment of new varieties or even incipient species. With regard to *Gongylonema neoplasticum*, he states his position very clearly:—

"Careful search has been made for some other morphological character in either sex that would enable *G. neoplasticum* to be definitely separated from the forms found in other hosts, but the results, so far, have been entirely negative. In every character studied the amount of individual variation is so great that the specimens from the rat usually fall between the extremes met with in specimens from other sources. . . .

"It is, therefore, a very difficult question whether *G. neoplasticum* should be considered a distinct species or not. It appears to depend upon the importance to be attached to a single character, limited to the male sex, viz., the length of the left spicule. Many helminthologists would, doubtless, consider this quite sufficient to constitute a 'good' species. The writer feels, however, that in view of the amount of variation possible in the forms from other hosts, and until a much larger number of males of *G. neoplasticum* has been examined, the evidence is rather strongly in favour of specific identity. This view does not, of course, exclude the possibility of the existence of a 'host-race,' or even an incipient species, confined to rodents. As in the other cases previously discussed, the question calls for careful experimental investigation by those able to undertake it."

And Professor Leiper made the experiment; an experiment which, no doubt, will be remembered long among helminthologists, biologists and physicians.

"If Baylis's opinion were well founded," says Professor Leiper, "it should have been possible to infest *Periplaneta americana* and then produce, in rats fed with these infected cockroaches, typical examples of the rat *Gongylonema neoplasticum*."

With this conviction, Professor Leiper began to feed his American cockroaches on the eggs brought back from the land of Columbus, maybe the very kind which on a previous occasion had stood on end! Then it was found that not only the cockroaches fed on Italian imported eggs, but the controls also, were stuffed with gongylonema worms, as though the very idea of the experiment had infected them.

The discovery that the cockroaches and the rats inhabiting the Gardens of the Zoological Society of London were naturally infested with *Gongylonema neoplasticum* may have suggested that time and money had been wasted in Italy, but, the necessary material being actually swarming at the "Gardens", it was decided to "attack the problem from another angle."

The new experiment, even more amazing in conception, shows a decided Solomonic touch.

"A further batch of cockroaches was secured, and those cockroaches found to be naturally infected were then split longitudinally into halves. These were fed respectively to sheep and laboratory-bred rats. Two series of experiments on these lines were made.

"In each series positive results followed both in sheep and rats. In the first series seventeen adult gongy-

lonemas were recovered from the rats and one from the sheep. In the second series four adults were found in the sheep and four also in the rats."

These the experiments, now the judgment.

"If Baylis's presumption had been correct, the worms developed in the rat would have differed from those developed in the sheep, in those morphological characters which distinguish the forms found naturally in the rat and those found naturally in the sheep and which have been regarded as the specific characters differentiating *Gongylonema neoplasticum* and *Gongylonema scutatum*. On the other hand, if his view had been incorrect we would have found that the forms developed in the rat and those developed in the sheep were morphologically identical, and identical too with the species naturally infesting the rat from which the cockroaches had acquired the infection utilized in the experiment."

Unfortunately Professor Leiper does not tell us which are the several "specific characters" by means of which he can distinguish *Gongylonema neoplasticum* from *Gongylonema scutatum*. From his "careful measurements" limited to the spicules, we may conclude that he knows no others.

"It follows then," says he, "that *Gongylonema neoplasticum can* develop under exceptional conditions, in sheep, but when it does so it can still be morphologically distinguished from the species of *Gongylonema scutatum*, which is the normal parasite of these animals."

Is it really possible that Professor Leiper goes to the trouble actually of making experiments to find out whether *Gongylonema scutatum* can change instanter to *Gongylonema neoplasticum* on visiting a rat, as he assumes that Dr. Baylis thinks? Could Professor Leiper really have thought that Baylis or I or anyone else could ever believe that a worm, well advanced in development (for such is a rat gongylonema arrived at the third and infective larval stage within its intermediate host), might turn into a different species the moment it found itself swallowed by the wrong host? Such transmutations do appear to happen at conjuring entertainments, but not in nature.

Thus ends this "valuable report" which the British Empire Cancer Campaign published in their Annual Report for 1925, and which the Scientific Advisory Committee of the Campaign "cordially endorse."

But why this attack?

In his retort to Dr. Baylis's letter, in the *British Medical Journal*, September 11, 1926, Professor Leiper says that his grant and ours were made at the same time, "with a wisdom and purpose I do not need to concern myself to discuss."

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed to the **Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be **sent to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, **which is Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints **if the order for these, with remittance, is given when MS. is sent in.** The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

Tropical Medicine and Hygiene

SEPTEMBER 15, 1926.

THE NATURE OF THE BACTERIOPHAGE

In an investigation into the nature of ultramicroscopic viruses carried out in 1915, Twort showed that on inoculating agar tubes with glycerinated calf-lymph and incubating them for 24 hours

at 37° C., watery-looking areas often developed, whilst in some of the tubes colonies of micrococci were obtained, and it was found that some of the colonies of the micrococci could not be subcultured and that if kept they became glossy and transparent, presenting a watery appearance. Young normal colonies, when inoculated with this material, developed a similar condition, whilst older colonies were more resistant and dead colonies were unaffected. On passing this watery material through Berkefeld filters, the filtrate, even after dilution a millionfold with water or saline, was capable of producing the same effect. The active agent was thermolabile, being destroyed at 60° C. Stock cultures of *Staphylococcus aureus* and *albus* were slightly affected in this way, whilst streptococci, tubercle bacilli and yeast remained unaffected. The ætiological agent could be promulgated from culture to culture for an indefinite period, continuously increasing in amount, whereas in the absence of living cultures it was incapable of propagation. Similar observations were also made with some intestinal bacteria.

Concerning the nature of the agent responsible for these phenomena, Twort made several interesting suggestions, namely, that the active material might be produced by the micrococcus, that the "virus" might be an ultramicroscopic organism, pathogenic for bacteria, that it might be living protoplasm which formed in definite individuals, or that it might be an enzyme with the power of growth.

The original communication of Twort excited little attention until 1917, when d'Herelle published the results of a similar investigation under the more effective title, "Sur un Microbe Invisible Antagoniste des Bacilles Dysentériques." d'Herelle considered that he had obtained from the stools of patients convalescent from bacillary dysentery a definite ultramicroscopic organism which was actively antagonistic to the dysentery bacillus of Shiga. He found that inoculation of young broth cultures of Shiga's bacillus with this ultramicroscopic organism growth of the culture was inhibited and the turbid culture became clear, the bacilli already present being dissolved. Further, the invisible micro-organism grew and multiplied, as it could be passed from culture to culture of the bacilli without losing its potency. In the absence of living bacteria it could not be propagated. When agar plates were spread with suspensions of the Shiga bacillus mixed in proper proportion with the invisible microbe, clear spots appeared in the film of bacterial growth. When first isolated the ultramicrobe was virulent for the Shiga bacillus only, but later acquired virulence *in vitro* for other bacteria. Lastly, although itself harmless to animals, this microbe was yet capable of rendering animals inoculated with it resistant to the action of the Shiga bacillus. Hence d'Herelle concluded that his active agent is an ultra-microscopic organism, giving to it the name *Bacteriophagum intestinale*: and that it constitutes our chief defence against infection by pathogenic bacteria.

The substance or agent obtained by Twort and that obtained by d'Herelle showed such similarity in their actions, namely, in bringing about the destruction and lysis of growing bacteria whilst itself increasing in amount in the bacterial cultures, that there can be little doubt that they were dealing with similar if not identical things.

The active agent has since been found to be widely distributed in nature, though it has chiefly been obtained from the intestinal tract of man and animals. Pathological tissues, exudates, bacterial cultures, soil and water, have also been employed as sources for the bacteriophage. It can only be propagated in living bacterial cultures, all attempts to propagate it in the absence of living growing bacteria having failed. From a study of the relationship between the multiplication of the bacteria and the increase in the bacteriophage, it has been concluded that the bacteriophage is a product of bacterial growth, rather than of bacterial disintegration.

The action of the bacteriophage upon bacteria may be summed up as follows: When exposed to the action of the bacteriophage many bacteria become phagogenic. Where grown in the presence of the bacteriophage the virulence of many organisms is altered, the cultural properties of the bacteria and the character of solid colonies may also be altered; the antigenic properties of bacteria may be modified by the bacteriophage, and the bacteria are killed and lyed.

The organisms most sensitive to the bacteriophage are the members of the typhoid-dysentery-colon group; less susceptible organisms include the diphtheria bacillus, the plague bacillus, the bacillus of hæmorrhagic septicæmia, staphylococci, streptococci, and the cholera vibrio. Variation in virulence is a marked characteristic of the bacteriophage, whilst it is extremely stable to influences like heat and chemical reagents. The bacteriophage also possesses antigenic properties and various antibodies can be obtained such as precipitins, agglutinins, and opsonins by appropriate manipulation. Lastly, its use as a prophylactive and curative agent has been recommended by d'Herelle.

As to the essential nature of the active agent two views have been held, namely, the original suggestion of d'Herelle, who claimed that it is an ultramicroscopic living organism capable of preying on living bacteria, as implied in the term bacteriophage, and the other that it is a ferment or catalytic agent for which Káteshima suggests the name "Ferment d'immunité bacteriolysant."

At the present time, however, it does not seem possible to arrive at a definite conclusion regarding the nature of the active bacteriophagous agent, and much yet remains to be learned about it before we can accept the original ultra-microbic hypothesis of d'Herelle as being thoroughly established.

F. E. T.

Annotations.

The Mechanism of Daughter Cyst Formation in Hydatid Disease (H. R. Dew, *Medical Journal of Australia*, April 24, 1926).—Daughter cysts in a typical hydatid cyst have an endogenous origin only. They usually arise by progressive evolution of the cells of the original germinal membrane or from brood capsules. More rarely they may develop from scolices. Their formation may be regarded as an expression of the powers of persistence of the parasitic cells. From thin-walled daughter cysts having the typical origin granddaughter cysts may arise in another way. This method consists of an external herniation of both layers at weakened parts of the laminated coat with secondary exclusion of the pouch. This is a rare method. Exogenous daughter cyst production from intracuticular nuclear masses, as usually described, does not occur. In secondary omental cysts, in bone and in the viscera of herbivora, peculiar cysts form which are due to external herniation of both layers with secondary closure and cyst formation, such herniations being dependent on the nature of the adventitious tissues.

Secondary echinococcosis is a well established condition and may occur in the abdomen, in the pleura or in operation wounds as the result of implantation of daughter cysts, brood capsules or scolices. Hydatid emboli and metastases can occur after intravascular rupture of cysts with carriage of brood capsules or scolices by the blood-stream and their survival and growth in new situations. This is the explanation of most cases of multiple cysts of the lungs, heart and brain.

Susceptibility and Resistance to Trypanosome Infections. Attempts at Immunization with Dead and Attenuated Trypanosomes (I. J. Kligler and I. Weitzmann, *Annals of Tropical Medicine and Parasitology*, June 24, 1926).—On account of technical difficulties experienced in collecting large amounts of trypanosomes with the primitive apparatus available, these experiments had to be temporarily suspended. Enough work has been done, however, to indicate that trypanosomes suspended in Bayer "205" behave quite differently from those suspended in saline, and that the animals so treated, instead of becoming hypersusceptible, develop a resistance quite distinct from that induced by the same quantity of the drug alone. The experiments reported give a clue to the nature of some of the pathological changes noted in trypanosome infection, at least in so far as they manifest themselves in experimental animals. The mechanism of the disease is evidently a complex one. First there is the unexplained mystery of the appearance and disappearance of parasites in the blood-stream, then there are the late manifestations of the disease, varying from mild swelling and œdema to severe ulceration and necrosis. In animals artificially sensitized swelling of the ears and eyelids occur promptly after the infection simultaneously with the invasion of the circulation. In normal animals swelling occurs only late in the disease, the fourth or fifth week; or, in other words, after the animal has become spontaneously sensitized by the absorption of the parasites or their products. The œdema and swelling noted in the later stages of the disease are, therefore, direct effects of the parasite and its products. If, however, the condition of treatment is varied and the trypanosomes are injected together with the drug "Bayer 205," an exactly opposite state is established in the animals; they manifest an increased resistance which in some of them may suffice to ward off an infection. This acquired resistance is not attributed to the protective action of the drug. The same phenomenon has already been observed in infected animals treated with "Bayer 205." It would appear that the drug combines in some way with the trypanosome cell producing a heterogenic antigen capable of stimulating the formation of specific antibodies. This may possibly be a demonstration of the type of a combined chemico-immuno-therapy supposed by Yorke to occur in malaria patients treated with quinine. The action of both quinine and "Bayer 205" is not, however, purely germicidal; associated with this property there is apparently also an immunizing activity which completes the cure and affords an increased resistance of greater or lesser duration to subsequent infection. Whether or not artificial immunization would result from the treatment of suitable animals with Hæmosporidia and quinine remains to be determined; the experiments reported suggest that animals may be rendered more resistant to trypanosome infection if treated with a mixture of trypanosomes and "Bayer 205."

Erysipelas. Observations on the Etiology and Treatment with Erysipelas Antistreptococcic Serum (K. E. Birkhaug, *Journal of the American Medical Association*, May 8, 1926).—Further experimental evidence is advanced to prove that the ætiologic agent in erysipelas is a specific type of *Streptococcus hæmolyticus* and that the serum produced with this specific type of micro-organism possesses very marked curative properties when administered early in the disease. Clinical trials in sixty moderately severe cases of erysipelas have demonstrated that intramuscular injection of erysipelas antistreptococcic serum, in amounts of 100 c.c. of the unconcentrated and from 15 c.c. to 20 c.c. of the concentrated serum, when administered during the first three days of the disease causes a prompt amelioration of toxic depression, a critical fall in temperature and pulse-rate, prompt fading of the erysipelatous lesions, and rapid absorption of the blebs and œdema within the affected areas. In late cases of erysipelas, the result of serum therapy is strikingly favourable in ameliorating the general toxic depression, although repeated injections of serum may be necessary completely to neutralize the circulating toxin in the patient's blood. Following each injection of the serum there is noted a critical drop in temperature and pulse to within normal limits from twelve to eight

hours after the injection of the serum; the symptoms may quickly return and a second dose may be necessary to bring about a complete recovery. By means of a skin test dose of toxin infected intradermally and simultaneously with the intramuscular therapeutic dose, it is possible to observe whether complete neutralization of the circulating toxins is accomplished or whether an inadequate dose of serum was administered to the patient to accomplish the cure of the disease. It is too early to state whether the serum is purely antitoxic in nature. Its influence on the rate of recurrence of erysipelas in patients having frequent attacks of the disease is also of great interest and will be studied further. It is hoped that serum sickness following the administration of large doses of antistreptococcic serum will be less severe and less frequent when refined globulin serum is used.

The Rôle of the Reticulo-Endothelial System in Immunity (C. W. Jungeblut and J. A. Berlot, *Journal of Experimental Medicine*, May 1, 1926).—Following massive doses of indian ink injected intravenously into guinea-pigs before a subcutaneous injection of diphtheria toxin-antitoxin mixture, no antitoxin was found in the blood-serum for three weeks, as indicated by intracutaneous tests, whereas an appreciable amount could be detected in non-blocked, immunized control animals. During the fourth week following immunization, the titre of the serum of blocked animals equalled that of non-blocked controls within the limits of the intracutaneous test dose. The smaller doses of India ink used in these experiments, given before immunization, had no stimulating effect on the production of diphtheria antitoxin, but, on the contrary, also inhibited the appearance of this antibody, although to a less extent.

The Relation between Atherosclerosis and Ingested Cholesterol in the Rabbit (S. Clarkson and J. H. Newburgh, *Journal of Experimental Medicine*, May 1, 1926).—The range of free cholesterol in the blood of rabbits, as determined by the Windaus method, varies from 35 mg. to 125 mg., with a mean of 71 mg. per 100 c.c. of blood. The small amount of cholesterol contained in the high protein diet used in earlier work and causing the atherosclerosis does not affect the blood-cholesterol nor does it cause arterial disease. In order to produce atherosclerosis it is necessary to feed at least ten times that amount of cholesterol. In rabbits receiving such amounts both hypercholesterolæmia and atherosclerosis occur, but it is not possible to establish any close parallelism between the two. High blood readings are found in rabbits with normal aortæ and atherosclerotic rabbits in this series sometimes have shown a normal blood-cholesterol. With still greater doses of cholesterol one finally reaches an amount which regularly produces hypercholesterolæmia and atherosclerosis within a few weeks. A new series of rabbits fed upon the high protein diet shows that those rabbits which become atherosclerotic also develop hypercholesterolæmia. This elevation of the blood-cholesterol is attributed to a metabolic disturbance directly referable to the excess of protein in the diet and not to its cholesterol content.

Studies on Pneumococcus Growth Inhibition (S. T. Wood, *Journal of Experimental Medicine*, May, 1926).—Employing a method described in an earlier publication for testing the pneumococcidal activity of serum-leucocyte mixtures, a study has been made of the pneumococcus-destroying properties of the blood of a relatively susceptible animal, the rabbit, for pneumococci of low virulence for the species. It was found that rabbit-leucocyte mixtures possessed the power to kill avirulent pneumococci in relatively large numbers, but failed to inhibit the growth of virulent organisms even in minute quantities. The results of numerous experiments in which all three types of pneumococci were employed indicated that the ability of a strain of pneumococcus to grow in rabbit blood is dependent on its virulence for the rabbit. The extreme susceptibility of the very young rabbit to strains of pneumococcus of low virulence for the full-grown animal was found to be associated with an absence of pneumococcidal properties in the blood of the young rabbit. These findings suggest that the relatively susceptible animals possess the same type of defence mechanism against pneumococcus infection as do the highly pneumococcus-resistant species.

A Study of the Incidence of Kala-azar in Certain Parts of North Behar (D. F. Micheal, *Indian Medical Research Memoirs*, February, 1926).—Kala-azar appears to be endemic in the District of Darbhanga and Muzaffarpur. Certain villages appear to be definite foci of infection, notably the villages of Rampur Bakhri, in the Muzaffarpur district and possibly also Mahespur, in the same district, and Mahamada, on the north side appears to be fairly heavily infected; exemplifying "site infection." Lack of conservancy, defects in domestic and personal hygiene and the presence of dirt in and around the houses are apparently definitely connected with the prevalence of the disease. The institution of hygienic measures in an infected area combined with the treatment of cases of the disease seems to lessen the incidence in a striking manner. The disease is most prevalent when humidity is prevalent and markedly less during dry weather. Children and young adults to a slightly lesser extent show the greatest degree to susceptibility to the disease. A point of interest is the comparative immunity to the disease which people of the sweeper class seem to enjoy. Not a single case has, to the author's knowledge, occurred amongst either the hospital sweepers or the Pusa Estate Conservancy Estab-

lishment or their families during the past four and a half years, while children of other servants in attendance on the sick in hospital have contracted the disease.

Current Literature.

THE AMERICAN JOURNAL OF TROPICAL MEDICINE, *May*, 1926.

Mosquito Species Control of Malaria (S. T. Darling).—These investigations were carried out in October, 1916. A preliminary field survey of a region where there was very severe endemic malaria in the rice fields of the Tjihœa Vlaagte showed that *A. aconita*, the anopheline carrier of the malaria, did not breed in the water of the rice fields which were under cultivation, but in neglected grassy irrigation ditches and grassy sodden rice paddies which were lying fallow. Based on these facts a notable reduction in the amount of malaria was made by instituting special regulations requiring the people regularly to clean and burn the irrigation ditches and to lay dry their rice fields after harvest, also to regulate the amount of water used for irrigation purposes avoiding its excessive use. It is suggested that every malarial problem should in like manner be defined first by field studies, for the actual breeding areas may be small and relatively easy to control, and it may be possible economically to use specific measures directed against all mosquitoes, and in this way avoid the unnecessary expenditure of time and money which has been not an uncommon feature of malarial control measures in many places.

The Prevalence and the Distribution of the Yellow Fever Mosquito Ædes ægypti (Linn.) in Venezuela (L. H. Dunn).—During the spring of 1925, twenty-six cities, towns and villages in various parts of the northern half of Venezuela were visited, and inspections were made to determine the extent to which the breeding of the yellow fever mosquito was occurring. The system of water supply and other conditions having potential influence on the breeding and distribution of this species were also inspected. In practically all the places visited, the system of water supply was found to be of such a nature as to necessitate the use of numerous containers, tinajas, ornamental fountains, barrels, ollas, pilas, filter stones, tanks and others, for water storage in the house, thus providing conditions favourable for the breeding of domestic mosquitoes in the habitations. In the better class houses of fifteen of the cities and towns there was a piped water supply, but in only one town, San Cristobal, was the supply sufficient to provide running water in the houses at all hours of the day and night. The other eleven towns and villages depended for their supply on rain water, wells and nearby rivers. In fourteen of the places visited, water was being sold in the streets by vendors. In all 3,506 houses were inspected and 10,229 water containers. No *Ædes ægypti* breeding place was found in three of the towns, the others were all positive.

The Occurrence of Quartan Malaria in the Low Coastal Regions of the State of Rio de Janeiro, Brazil. An Epidemiological Study (N. C. Davis and M. F. Boyd).—Studies within certain areas within the low coastal region of the State of Rio de Janeiro, Brazil, have revealed a very small number of infections with *Plasmodium malariæ*. Reasons are given for believing that some infections have been missed and others wrongly diagnosed at the time of the surveys. The data indicate that the quartan rate probably fluctuates in the same manner as that of the other malaria infections. The persistence of *P. malariæ* blood infections during months of low fever incidence has been verified. The geographical distribution of the *P. malariæ* infections reveals the presence of definite foci which consistently produce new cases each year. There is no obvious reason why the rate should continue so low, i.e., why there is no epidemic increase in quartan comparable to that of the other malaria fevers.

The Isolation and Cultivation of Herpetomonas Muscæ Domesticæ (R. W. Glaser).—A method is described whereby a flagellate protozoan (*Herpetomonas muscæ domesticæ*) parasitic in the alimentary tract of adult house-flies can be freed from the intestinal flora and grown indefinitely in pure culture. Previous attempts at cultivating many protozoa parasitic in the alimentary tract of insects have usually failed due to the inhibiting effect of the bacterial flora which is difficult to separate from the protozoa. A detailed description is given of the process for the purification and isolation of the flagellate, and a detailed study of the growth characters and of the living micro-organism is presented and by a study of fixed and stained preparations the morphology of the cultural forms is described and compared with the forms found in flies. It has been proved that the flagellate cultivated is actually *H. muscæ domesticæ*, and additional proof is furnished that the genus *Herpetomonas* is closely related to the genus *Leishmania*.

The Common Picture of Sprue, Pernicious Anæmia, and Combined Degeneration (A. C. Reed and H. A. Wycoff).—The purpose of the authors has been to show that a common clinical entity is embraced by the accepted diagnosis of tropical sprue, pernicious anæmia, and subacute combined degeneration of the spinal cord. There exists a common toxin manifesting different intensities in each disease, which attacks the blood, the gastro-intestinal tract and the spinal cord. It is also suggested that the toxin is more likely a protein or type toxin than a unit chemical substance, and that its place of origin is in the digestive canal. There has been no evidence that either Protozoa or Metazoa is necessary for production of such a toxin. Either or both might well be an associated cause or secondary invaders obtaining foothold because of the damage already done to the intestine. Cases are reported to illustrate the points at issue.

Original Communication.

THE CAUTERIZATION OF ADHESIONS IN ARTIFICIAL PNEUMOTHORAX TREATMENT OF PULMONARY TUBERCULOSIS. TECHNIQUE AND INDICATIONS, TOGETHER WITH A SURVEY OF RESULTS OBTAINED.[1]

By Professor H. C. JACOBAEUS.

FOR about fifteen years I have occupied myself with endoscopy of the serous cavities, peritoneum and pleura. At first, I was interested only in the diagnostic advantages which could be gained by such a method. In a case of ascites, after tapping and replacing the fluid by air I could by endoscopy get a clear view of the abdominal organs. There was thus no difficulty in diagnosing liver cirrhosis, Pick's disease, carcinoma and tuberculosis of the peritoneum, &c.

Without doubt, the predominant value of endoscopy centres around the examination of the pleural cavities, the so-called thoracoscopy. With regard to the chest cavity we have, as we know, nothing corresponding to exploratory laparotomy. Further, thoracoscopy is so simple a method that it can be performed without inconvenience in every exudative pleurisy which is available to a thoracocentesis. The ocular examination of the pleural surfaces is in most cases relatively complete. In cases of so-called idiopathic pleurisy I have also succeeded in finding distinct tubercles in most of them. For the differential diagnosis of tumours and pleurisy of other origin, thoracoscopy is likewise of no small value. After some practice it is at least possible, with some certainty, to differentiate between tumour metastases and tuberculous changes. In doubtful cases, one can by test excision, under guidance of the thoracoscopy, decide the nature of the pleurisy in the special case. Even solid intrathoracic tumours can be observed by thoracoscopy, and their relations to neighbouring structures, lung, thoracic wall, &c., be determined much more clearly than by any other method. By this an evident practical advantage for an intended operation is gained.

The second and, from a practical point of view, the most important field for the use of thoracoscopy comprises those surgical operations which can be performed directly under guidance of this method. By thoracoscopy in the pneumothorax treatment of lung tuberculosis an especially fine picture of string-like adhesions between lung and thoracic wall is obtained. This caused me to try to work out a method under the guidance of the thoracoscope to remove such adhesions as impede the treatment. It is a well-known experience that a single string-shaped adhesion, which attached the lung to the thoracic wall and thereby prevents collapse of a cavity, can cause the failure of the whole treatment in artificial pneumothorax. A paper by Gravesen, from Professor Saugman's sanatorium, contains the following tables which prove the injurious results of these adhesions:—

(1) Cases with complete pneumothorax without adhesions (3 to 13 years after discharge).

Able to work	23	(62·1 per cent.)
Not able to work	1	(2·75 per cent.)
Died from tuberculosis	11	(29·65 per cent.)
Died from other causes	1	(2·75 per cent.)
Unknown	1	(2·75 per cent.)
	37	

(2) Cases with complete pneumothorax, but with localized, extended adhesions.

Able to work	14	(33⅓ per cent.)
Died from tuberculosis	28	(66⅔ per cent.)
	42	

(3) Cases with incomplete pneumothorax with larger or smaller extended adhesions.

Able to work	5	(11·1 per cent.)
Died from tuberculosis	39	(86·7 per cent.)
Died from other causes	1	(2·2 per cent.)
	45	

The injurious influence of the adhesions is plainly demonstrated by these tables, which also give one an impression of their frequency. I cannot here enter into the different methods attempted by others to remove such adhesions, I can only say that none of them has attained practical importance.

As it is rather easy to observe the above adhesions by thoracoscopy, the idea occurred to cauterize them by introducing a galvanocautery through another opening, under the guidance of the thoracoscope. My first attempts were made in 1913, and since then I have performed operations on altogether 170 cases, of which only 150 will be more closely dealt with here, the remainder having only recently been operated upon.

The method has also been adopted in most countries in Europe, in Germany by Unverricht, Gehrcke and others in Denmark by Gravesen, Kristofferson and others, in Norway by Holmboe, in France by Hervé and others, in Spain by Sayé, in Switzerland by Pignet, Giraud and Maurer, in U.S.A. by Singer, &c.

TECHNIQUE.

The preparations for the operation need not be very extensive, I do not consider it necessary to give the patient morphine before the operation. If he is very anxious I find it better to give him bromide, luminal, or similar remedies. It is of great importance to be sure that the electrical apparatus is in perfect working order.

Immediately before the operation I am accustomed, after the method of Saugman, to make a fluoroscopic examination and draw the points of attachments of the adhesions and their extensions on the patient's chest. This makes a very good guide when choosing the place for introducing the thoracoscope, it being always most advisable to have the light as near the field of operation as possible.

[1] From the Medical Service II of the Serafimerlasarett, Stockholm, Sweden (Professor H. C. Jacobaeus, Director).

The patient is put on his healthy side with a big, hard roll-pad under the chest as near the arm as possible (fig. 1). He has a smaller pillow under his head. The idea of placing him thus is to get the pneumothorax half of the chest as convex as possible. It is also advisable to let the patient's arm on the operated side lie upward and forward, so that the scapula is pulled upward and outward. The chest wall gets thinner, the interspaces are more easily felt, and the local anæsthetic can be given with more confidence and the thoracoscope can be introduced higher up on the chest wall without difficulty.

At the operation proper I first introduce the trocar for the thoracoscope after a careful local anæsthesia, generally one to three interspaces below the level where the adhesions are marked by means of the fluoroscope. This is, of course, not possible if the adhesions are localized to the apex, but one has to try to find an interspace as high up in the interscapular area as possible. The higher up on the

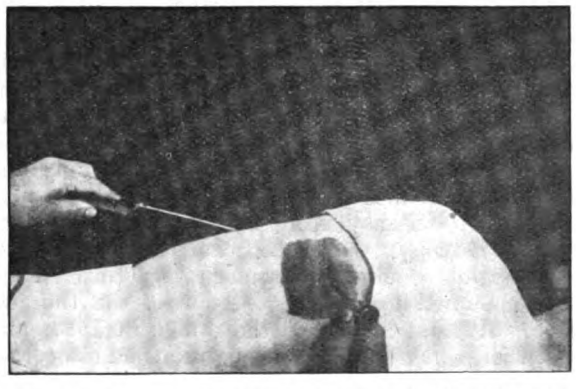

Fig. 1.—The position of the patient—on his healthy side—at the operation. The seat of insertion of the thoracoscope on the back and the point of insertion of the galvano-cautery and its direction of application in the case of highly localized adhesions.

chest wall one gets, the thicker the muscles are, and the more difficult it is to make the anæsthesia quite effective.

The thoracoscopy, which is first performed, aims to give as complete an orientation of the conditions in the pleural cavity as possible. If it is a matter of single string-shaped adhesions, then it is rather easy. In introducing the thoracoscope rather far back near the spine, before the thicker back musculature begins, one gets the longitudinal direction of the lung at right angles to the thoracoscope. In this way it is possible to get a survey of the lung in its longitudinal direction. As the adhesions generally extend from the lung to the chest wall at a more or less wide angle, it is evident that with this direction of the thoracoscope and the field of vision it will be easy enough to find and localize the adhesions in question.

If the adhesions are membrane-like, the difficulties are greater and no rule can be established. The same is the case if the lung is broadly fixed to the anterior or posterior chest wall and also with narrow strings in different directions. Only experience can solve the difficulties in such cases. The other stage of the operation, the cauterization itself, then begins. For insertion of the galvano-cautery I have employed of late a trocar of the same diameter as that through which the thoracoscope is introduced. One advantage of this is the production of a space between the trocar and the cautery enabling the respiratory air to pass to and fro. The smoke produced through the burning process is thereby automatically eliminated. The second advantage is that one is able to introduce the thoracoscope through either of the trocars. This is of no small consequence in the case of several adhesions being localized to different parts of the pleural cavity. In some cases it may be easier to see and reach the adhesions with the thoracoscope introduced from the front, in other cases contrariwise. When operating, therefore, I insert one trocar from the back and a second one from the front. The level at which the adhesions are situated determine whether the trocars should be inserted high up or low down on the chest.

The platinum needle has, during the past year, been slightly altered in a way that has proved of great practicability, in that the point has been made in the shape of a hook by which the adhesions can be easily caught and prevented from slipping off during the burning operation.

The galvano-cautery is carefully introduced in the direction where the adhesion is calculated to be situated. With some experience this is rather easy and I have many times introduced the cauterizer directly on the adhesion which I desired to burn off. If this does not immediately succeed, the adhesion has to be found with the thoracoscope in the thoracic cavity which, to begin with, may cause certain difficulties. After this, the platinum point has to be placed on the adhesion at the spot where it has to be cauterized. As regards a general rule, with string-shaped adhesions, I perform the cauterization where the adhesion is most narrow. If a cavity is visible on the X-ray film, immediately below where the adhesion is fixed to the lung, the cauterization should be made as close to the chest wall as possible. Technically this is slightly more difficult, but it causes the patient considerably more pain. In these cases the patient has really a sensation of a burning pain which extends diffusely throughout the whole half of the chest. Where it is a question of apex adhesions the pains radiate to the arm. If the cauterization is performed at a little distance (2 to 3 cm.) from the chest wall, the patient has scarcely any sensation of the cauterization, but has mostly a disagreeable feeling of pulling at the adhesion caused by the pressure of the galvano-cautery.

At the cauterization itself one has to decide the intensity of the glow of the galvano-cautery. This is of importance because of the possibility of hæmorrhage. After switching on the current, it ought to take five to ten seconds before the platinum needle becomes aglow, and then only a red glow. A white heat is absolutely dangerous.

The cauterization ought to proceed very slowly. In slightly pressing the galvano-cautery against the adhesion one feels how fibre after fibre is loosening. Then, bit by bit the adhesion can be burnt off, until at last it is completely severed, when the lung collapses by its own weight and usually an interval of several centimetres appears between the two burnt off stumps of the adhesions.

As above mentioned, the immediate danger of cauterization is hæmorrhage. The danger of a serious hæmorrhage arises if, in the cauterization, one penetrates the lung and there cuts into an artery.

I have only once in my experience had a hæmorrhage of any consequence. In this case there was quite a narrow thread-like adhesion. The cauterization went very easily and quickly, in a fractional part of a minute, but afterwards the parietal stump of the adhesion dripped blood rather rapidly. In all, the hæmorrhage might be estimated at the most to have been about 200 c.c. Other authors, such as Saugman and Skärgard, have at times had lesser hæmorrhages, which were considered to be caused by too strong a glow, at least by the latter operator.

Only once in all the operations known to me (thus far in more than 400 cases) has a fatal hæmorrhage ensued. In one case, where the operation, performed by Dahlstedt, proceeded quickly, a severe hæmorrhage suddenly set in. The blood spurted into the thoracic cavity. The prism of the thoracoscope became constantly splashed, and it was therefore impossible, under its guidance, to get at the bleeding point with the galvano-cautery, in order to stop the bleeding by a new cauterization. The bleeding became so severe that the patient lost consciousness for a moment. In another case, where the operation was performed by Skärgard, a similar arterial bleeding arose from the lung. Here the operator succeeded in stopping the bleeding by continuing to burn the bleeding part proximally. I myself have stopped quite small hæmorrhages by holding the galvano-cautery close to the bleeding place. Should a large arterial bleeding arise I think it best to get as high a pressure as possible in the pleural cavity in question. The best method to this end should be to fill it up with saline solution, which ought to stop the bleeding.

I should like to state, as my conception of the cause of the bleeding and its prevention, that:—

(1) The more severe hæmorrhages probably arise principally from cauterization of the lung itself.

(2) They can most surely be prevented by using a weak glow and by burning as slowly as possible.

In a previous paper I have, from a practical point of view, classified the adhesions into three different groups: (1) apex; (2) lateral; and (3) diaphragmatic. The limit between at least the first two classes is rather vague, and I have, therefore, fixed the second rib as the line between them.

The most common ones are of group 2, the lateral adhesions. A part of them borders on group 1, where we find the largest and thickest adhesions below the second rib and some smaller string-shaped ones higher up in the cupola itself. Or we find membrane-like adhesions, which continue toward the apex above the second rib. The reason why I have separated an upper group is because of the more difficult technique which is required for the apex adhesions. The technique of these cauterizations has for its object to introduce the thoracoscope as high up as possible in the back, after the scapula has been pushed upward and forward.

The difficulty in cauterizing these adhesions lies in the following circumstances. Most cavities exist in the apex of the lung, and these are fastened to the cupola itself by short adhesions. The movability of the lung in respiration is rather small here, and from this it follows that these adhesions during life are exposed to relatively little tension and are therefore short and consequently there is a risk of burning the lung. At all events, it is necessary to burn as close to the chest wall as possible, which often causes this operation to be rather painful.

The lateral adhesions from the area below the second rib to the diaphragm are the most numerous. They are mostly quite easy to get at. Diaphragmatic adhesions also deserve closer consideration. In all my cases of this kind it has happened that the lung above has been attached to the chest wall to such a high degree that it has not been possible to undertake any cauterization there. Besides, there have existed from one to several narrow, string-shaped adhesions to the diaphragm. By burning them off it is possible to get the lung pushed up, and thereby also obtain a more complete collapse of the lung. From a technical point of view, the cauterization presents the difficulty that the patient must hold his breath during the cauterization, because otherwise the adhesions are in constant movement. If the cauterization succeeds in a single burning there is no difficulty, but if, as is generally the case, the galvano-cautery has to be applied several times on this swinging band, it can be very troublesome technically to remove such adhesions. An advantage is that the burning of such adhesions is completely painless. Another question is the practical use of cauterizing such adhesions. In my experience it is only in exceptional cases—only in one of my four cases—that it is of any real benefit to do so.

Indications.

It is necessary before each cauterization to have an X-ray photograph of the collapsed lung with its adhesions. The first question that arises is, then, how much can be judged from the X-ray picture about the prospects of a successful operation? In cases where only one or two isolated, string-shaped, long adhesions are to be found the indications are easy, and one can assume at once that from a technical point of view it is possible and very likely easy to cauterize the adhesions.

It is more difficult to select those cases in which the X-ray apparently shows too thick adhesions, or in which relations are perfectly indistinct and one does not know the nature and extent of the ad-

hesions. In the latter case one has to rely on the thoracoscope.

I can state that in the majority of the cauterizations there have always been found more adhesions than were visible on the X-ray picture. This is generally of less importance, because the unobserved adhesions are, as a rule, so thin that they do not present any serious obstacle to cauterization. Experience shows, however, that cauterization in most cases is more difficult than can be expected from the X-ray picture.

From both the literature and private information, I have become familiar with cases in which attempted thoracotomy has revealed the adhesions to be much thicker than was originally supposed. In these cases the operation was consequently more difficult and involved more extensive interference than had been anticipated.

The other method to determine the possibility of operation is thoracoscopy. This will, according to my opinion, become more and more important in deciding the possibility of operation in the more serious cases, not only with regard to cauterization but also other surgical methods.

By thoracoscopy one gets a perfectly accurate picture of narrow, string-shaped adhesions, up to the thickness of a small finger. The difficulties appear in the case of membrane-like adhesions and those attached to the surface.

In perhaps the majority of cases one can see the compressed lung in its proper colour, greyish-red, with distinct vessels in its longitudinal direction. The tissue is loose and spongy when pressed with the galvano-cautery. Often the adhesion runs like a membrane along the ribs. It vibrates when the patient coughs or is shaken. In these cases there is also a transparent bluish colour. These adhesions are the most favourable ones for cauterization, which may be done easily, rapidly, and without pain worth mentioning. The danger of hæmorrhage can surely not be great.

I have burnt off adhesions with rather large, even varicose, vessels without any bleeding whatever.

The string-shaped, stretched adhesions, thinner than a pencil may well contain lung tissue and perhaps also offshoots from cavities, but they are still, in my opinion, not dangerous to burn off, just as in the case of hæmorrhages one has to attach a certain importance to the immediate, marked shrinkage of the adhesion after cauterization in preventing tuberculous infection of the pleura.

While working with thoracoscopy, one can see the adhesion stumps shrink to half of their original size or more within a few minutes. Without doubt, offshoots from cavities which exist there must be compressed and obliterated. This sounds bold and hypothetical, but I believe that it is so. If these adhesions are microscopically examined one finds not infrequently offshoots from cavities filled with necrotic tissue. To date, several hundred adhesions have been burnt off, and in only a very few cases has a cavity been opened, with resulting mixed infection in the pleura. The long and severe pleurisies after the operation seemed to be caused by the opening of tuberculosis foci by the cauterization, and then the infection spreads to the pleural cavity. I have not infrequently had string-shaped adhesions, which at X-ray examination and on thoracoscopy, have been technically easy and possible to burn off, but in which I have, nevertheless, refrained from doing, because it was necessary to consider the clinical effect obtainable by the removal of the adhesions in question. According to Saugman's and Gravesen's statistics, the difference between the prognosis of those cases with and those without adhesions is so great that practically all string-shaped adhesions, which are technically possible of removal, provide an indication for cauterization. I believe that as long as one cannot, as is now the case, decide upon the risks of the operation, one ought to have some more definite indications. If, for instance, the case is one of a patient whose general condition is excellent, who has no sputum and whose compressed lung shows no sign of cavity, I have not considered the indications sufficient for operation.

The unlimited possibilities of variation are, however, such that this rule cannot be absolute. If a case has a cavity in the lung, and is without tubercle bacilli or sputum, and has the lung expanded by adhesions, and is technically operable, then I consider it one for cauterization. In such a case sputum or bacilli usually appear again sooner or later.

In some cases, as Holmboe and myself have pointed out, there is no sputum, but after every introduction of gas the patient suffers an intense irritating cough for several days, which bothers him a great deal and prevents sleep. In these the adhesions are, as a rule, very narrow and sometimes they do not even appear on the X-ray photograph I have not seen such symptoms in cases with extensive adhesions. I consider cases with such symptoms as full indications for cauterization, so much the more as these adhesions for the most part are very easy to remove.

Finally, the presence of an exudate influences the indications for operation. According to my experience an existing pleurisy always becomes worse after a cauterization. I have in two cases seen a serious empyema set in as a nearly direct consequence of this. With a pleuritic exudate present, it is also, as already mentioned, difficult to determine the operative possibilities. The pleural surfaces are covered with fibrinous membrane and granulation tissue. The difference between lung and adhesion is not apparent; everything appears on a greyish background. In the cauterization itself one has to proceed with great caution, but it is not always as difficult as imagined. The adhesions appear very thick, but their outer layer is mostly loose granulated tissue, which is easy to penetrate. During pleurisy, one's net impression is that no operation should be performed unless there are good prospects of a decidedly favourable effect.

Tuberculosis of the larynx is no contra-indicati n

Tuberculosis in the other lung permits of cauterization only if it is necessary to continue the patient's pneumothorax. In cases of tuberculosis of other organs the same rule holds.

A summary of the indications for cauterization of adhesions will, therefore, be as follows:—

(1) String-shaped adhesions up to the thickness of a little finger, found by X-ray examination, can always be burnt off, and this operation can, as a matter of fact, be done without great risk.

(2) Membrane-shaped adhesions are similarly suitable for cauterization. The possibility of operating upon them is best decided by thoracoscopy.

(3) With regard to surface adhesions, there is need for great precaution, and one should burn off only the granulation tissue which attaches the lung to the chest wall. By cauterizing the lung itself there is the risk of hæmorrhages as well as opening of tuberculosis foci and cavities, with a consequent infection of the pleura.

Critical Survey of Operations thus far Performed.

In a critical survey of 150 cases, I will first consider those complications which followed operation immediately or ultimately. To begin with, we must refer to the skin emphysema of greater or less degree which appears at the points of puncture of the chest wall. This complication can cause trouble for two or three days, after which it disappears and is of no further consequence.

Of greater importance, however, are the pleuritic exudates which may follow operation. In the following table I have set down the various results which occurred in my cases:—

1.—Cases without exudate or with slight exudate ...	111
2.—Cases with long-lasting exudate and fever ...	21
3.—Cases with long-lasting exudate with empyema ...	14
4.—Cases with exudate, first appearing one to three three months after operation	4
	150

The first group is made up of cases the clinical course of which proceeded most favourably. After a few days' pyrexia the temperature returned to what it was before the operation. In cases with effusion this has rarely reached above the diaphragm and has generally been absorbed in one to two weeks.

In my opinion, therefore, these effusions are merely reactionary results of the thermic and mechanical interference at the operation, and do not in any way affect the clinical results.

The second group is comprised of cases where the effusion has been quantitatively much greater, filling up at least half of the pleural sac and remaining for several weeks or months. On examination of the exudate tubercle bacilli have been found on inoculation of animals. In my opinion tuberculous foci have become opened in the process of cauterization, the pleura thereby being infected. The temperature in these cases has been high and the general condition adversely affected for a long time. A good result, even if belated, however, has generally been obtained.

The third group is the most important, because of complications, it involves the most serious one. Two types may be distinguished. One of them is characterized by symptoms of acute pleurisy of a severe kind setting in soon after the operation with sharp pains in the side, dyspnœa, high temperature and the general condition much affected. Tubercle bacilli are frequently found in direct preparations. Symptoms supervened pointing to "valvular" pneumothorax from the breaking of a cavity and before long there were signs of pyo-pneumothorax. The author has had two such cases where death followed very soon after the operation. In a third case the progress was most favourable after the operation, the lung with its cavity becoming completely collapsed; three weeks after the operation, however, the cavity broke with a subsequent " valvular " pneumothorax, pyo-pneumothorax and later death. One was not able to definitely establish here to what extent the cauterization was to be blamed for the result. Had the cavity been opened in conjunction with the operation, severe symptoms, such as described above, would probably have arisen immediately afterwards and not after such a long time. A thoracoscopy gave no information as regards the seat of the perforation, and autopsy being refused the origin of the empyema was never revealed. The second type is characterized by an initial serous pleurisy that gradually passes into an empyema. This has been the event in most of the cases, the prognosis then being more favourable, many of them having recovered.

The last group is of less interest. Four of them developed effusions one to three months after the operation. Pleuritic effusion occurring so commonly in the course of treatment by pneumothorax renders it is impossible to say whether the pleurisy in these cases was of spontaneous nature or developed as a result of the operation.

I will therefore pass on to the results obtained by the operation.

Number of cases	Technically successful cauterizations	Clinically successful results	Incomplete cauterizations
150 ...	121 ...	99 ...	29

On the whole these figures are similar to those already published in previous works, with an increase, however, of the good results. This is primarily due to a further knowledge as regards selection of suitable cases but also to some extent to an increased technical skill.

The group of technically successful cauterizations includes all cases where the adhesions have been removed to such an extent as to render the lung completely compressed. In the group of clinically successful cases I have collected those where after a shorter or longer time—one week to a month and sometimes even longer—the sputum has ceased and the temperature has become normal. We are only concerned here, however, with the immediate results after one or several years.

The last group (the incompletely cauterized adhesions) is comprised of those cases where, as implied by the heading, the lung has not been freed from its attachment to the chest wall to such an

extent as to permit of sufficient collapse. However well defined this group may be, it is not always easy to make a distinction between these cases and those technically successful. Border-land cases exist, where the lung has been freed for the most part, but where it might take quite a long time, sometimes several months, until a clinically good result may be demonstrated. In such cases one must bear in mind the possibility of healing taking place through Nature's own resources.

It is of great interest to study more closely the twenty-two cases where the operation was technically successful but clinically where no good results followed. In six of them a pleurisy was present before the operation, in two of which there was even a chronic empyema. The condition became aggravated, varying somewhat in the different cases but with the general state of health much lowered in all of them. The clinical result, therefore, was bad, although it is not so easy to say to what extent this was due to the operation. In some of the cases this had undoubtedly a deleterious effect.

Out of nine cases, in which the pleura before the operation had been normal, two developed acute empyema with alarming symptoms, death taking place in the short time of ten to twenty days. In the remaining cases there was first an ordinary serous pleurisy, that later, after a shorter or longer interval, became purulent.

In four cases no pleurisy developed, but the changes present in the other lung before the operation became aggravated. In another case a fatal tuberculous enteritis supervened. In a third case the patient suffered from severe diabetes; the operation was an extensive one and although some temporary improvement followed upon treatment with insulin, the patient gradually developed empyema and progressive tuberculosis.

In a final case with a poor general condition an extensive cauterization was undertaken with a technically good result. Some days later a severe attack of asthma set in, from which the patient had been suffering for several years. One was not able to utilize the results obtained by the operation and the patient died.

In cases incompletely cauterized no harm has generally resulted from the operation, this being interrupted in good time, as it was generally obvious at a fairly early stage that no success was to be attained. In not a few cases—perhaps half the number—has the operation been performed in strange places for the purpose of demonstrating the technique, and under these circumstances it was impossible already from the start to make the operation complete.

Two cases are deserving of great attention, inasmuch as they developed an adhesive pleurisy after the operation, necessitating interruption of the pneumothorax treatment after some time with a reverse effect to what had been desired.

It is of great interest to note the results with reference to the different kinds of adhesions according to the basis of classification already evolved. Out of 74 string-shaped adhesions in altoge technically successful cases there was a fa result in 64 and an unfavourable one in total figure for the membranous adhesion of which 23 were favourable and 4 unfav and finally for the surface adhesions—20 all—there were 13 favourable and 7 bad

From the point of view of the localizatior adhesions, in the thoracic cavity, on the othe they are distributed as follows. There are cases of diaphragmatic adhesions, in one which the result was satisfactory. It is prob very exceptional cases that these adhesions satisfactorily dealt with by operation.

Of the remaining groups the adhesions are localized to the apex in 33 cases and laterall ated in 113. It may be mentioned for comp that in the first 50 cases published the adh were apical in 5 cases, lateral in 42 anc phragmatic in 3 cases. It is clear from this in direction changes tend to occur.

Out of 33 cases with apical adhesions suff collapse was obtained in 30 with good resul 19. Of the remaining 113 cases with latera hesions technically successful cauterizations performed in 89, in only 7 of which the results inferior.

To sum up the above results, it may be seen these are less favourable in the case of apical diaphragmatic adhesions where also the opera technique is very much more difficult. The results are undoubtedly obtained with the la adhesions, notwithstanding the fact that operat are more often undertaken here, technically possible of being completed.

As has already been repeatedly pointed the above results of the operation are imme and do not represent any remote results. Thr the operation the patient has been temporarily from sputum and bacilli. The subsequent pro has nothing to do with the operation and is su to the same factors that have a bearing upon case undergoing treatment by pneumothorax. benefit of the operation in that case is to be in a better prognosis, in that recovery whicl cording to Gravesen's figures, takes place in 1 cent. to 33 per cent. of cases with adhesions, to 70·2 per cent., confirmed after several ye

Among authors Gravesen is the only one gives in tabular form his material one to six after the operation, and has arrived at the fol result. I have unfortunately been unable to any after-examinations of cases in my ext material, the patients having been operated in so many distant places in different cor A rough estimate, however, gives a much percentage of recoveries, rather below than 50 per cent., primarily due to a progressive culous infection in the other lung or some part of the body.

Able to work	17	(65 per cen
Ill with tuberculosis ...	1	(4 per cen
Died from tuberculosis ...	8	(31 per cer
Total ...	26	

Although Gravesen's figures are too small to justify any general conclusions to be drawn from them, they are nevertheless of the greatest interest. The results are in my opinion better than could be expected. They approach as near as possible the statistics given by the same author concerning uncomplicated pneumothorax, where the percentage of those capable of working was 70 per cent. These figures are also of interest from this point of view, that the cases with adhesions are to be considered as a more advanced and severe type of pulmonary tuberculosis as compared with that in uncomplicated cases of pneumothorax.

Extracts from the Casuistic.

Case 132, Miss B.B., born March 3, 1895.—No heredity for tuberculosis. In December, 1920, left-sided pneumonia, after that weak for a long time; only in July, 1921, restored to health. In August, 1923, consulted for the lungs, because she had coughed the whole time since 1921, and now lung tuberculosis was proved. Pneumothorax established January 31, 1924. May 17, 1924, cauterization of some adhesions on the upper part of the lung: only partial success. Three weeks after the cauterization rising temperature and exudate, which had diminished since November 24, simultaneously got worse and again subfebrile temperature. Lately better and afebrile, except at premenstrual periods. Sputa, which before November, 1924, were absent, have since then been about 10 to 15 c.c. Tubercle bacilli always present.

Admitted February 16, 1925. General condition good. X-ray examination February 17, 1925. Left-sided pneumothorax with good compression of the lower part of the lung. In the upper part a cavity of quite the size of a goose's egg. The upper part of the lung is kept expanded by a broad, outward, well-defined adhesion opposite the clavicle and the first rib. In sinus an exudate which in a sitting position reaches to about the level of the diaphragm cupola. (Fig. 2.)

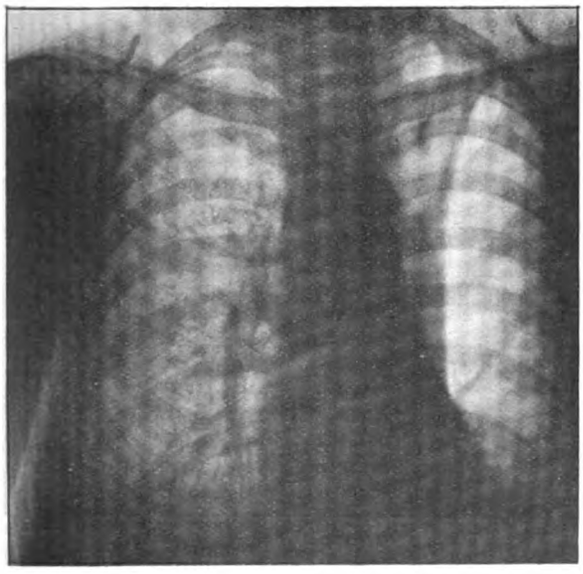

Fig. 2.—Case 132. Cavity in the upper part of the lung, the size of a goose egg, which is kept expanded by a short adhesion opposite the clavicle and the first rib. The dark defined shadow in the middle of the cavity represents an adhesion, which is attached to the front side of thorax in a frontal direction.

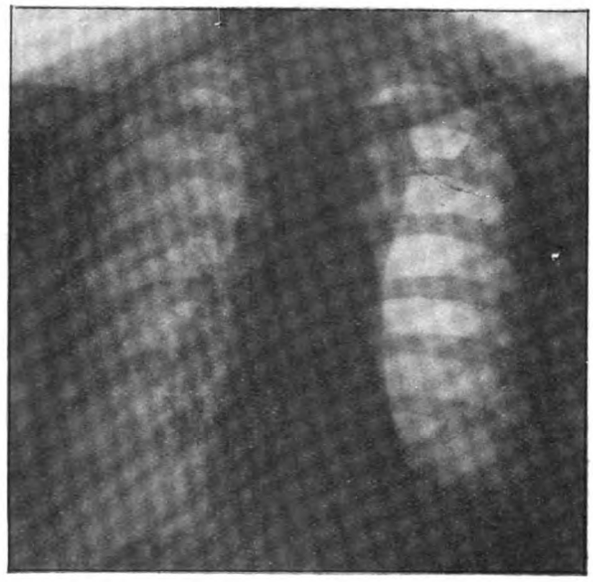

Fig. 3.—The same case after the first operation. A small adhesion in the middle of the apex area still remains.

February 23, 1925.—First operation.—On thoracoscopy pleura parietalis normal, pleura pulmonalis greatly thickened, grey-white above the upper lobe. Laterally upwards a transverse adhesion with free edge forwards. Posteriorly it continues upwards, so that the apex cannot be seen. There is, moreover, visible a string-like adhesion of the thickness of an ordinary string and another one thicker than the little finger. The thick adhesion was first cauterized away from the free edge. It proved to be a surface adhesion which extended obliquely backwards and upwards over the apex of the lung. It was cauterized quite close to the pleura parietalis, across at least one and a half interstices. The furthest part could not be removed on account of the vaulting of the lung. The lung has collapsed several cm. After that the two above-mentioned adhesions were easily cauterized, and also two string-like adhesions in front. Remarkably slight pains during the operation (25 minutes). Progress after operation favourable.

X-ray examination March 7, 1925.—The previously described ribbon-like adhesion laterally has disappeared and the apex area seems more collapsed than before. There is, however, on the lung a small dentiform curve, corresponding to the place of the old adhesion. Over the apex area remains a string-like adhesion. (Fig. 3.)

March 13, 1925.—Second operation.—On thoracoscopy the lung seems considerably better collapsed than before. The extensive wound upwards is

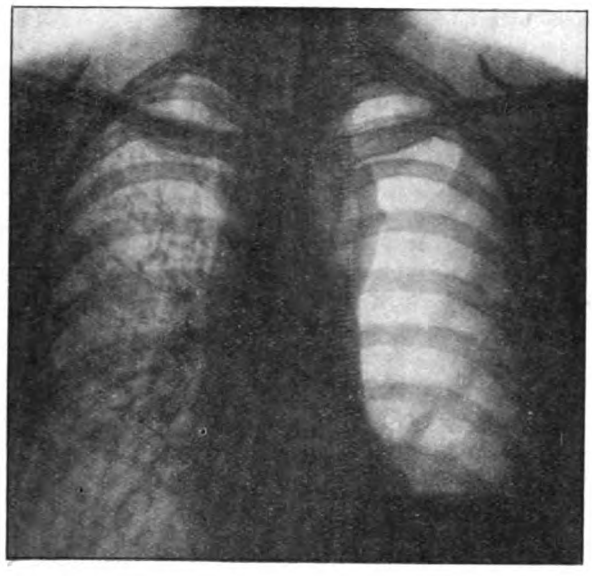

FIG. 4.—The same case some days after the second operation, when the lung is free upwards. Remarkable is the gradual thickening of the cavity wall after each operation.

covered by a thin layer of grey-white granulation tissue. Uppermost in the pleural cupola itself there remains a broad flap of the adhesion, but its thickness cannot be determined. The burning was rather easy, although the adhesion was fairly fibrous. Further down on the lung somewhat anteriorly there is a fibrin-covered, rind-like spot, about the size of a shilling, surrounded by subserous hæmorrhages. No pain, no bleeding. Progress after operation exceedingly favourable.

X-ray examination March 24, 1925.—The adhesion, stretching towards the apex area, which was described on the previous radiogram, is now cauterised, the lung further collapsed, so that the upper part of the cavity lies at the lower edge of the sternoclavicular joint. The cavity measures 1 cm. in width and 5·5 cm. in height. (Fig. 4.)

March 28, 1925.—The patient could leave the hospital for policlinical treatment. During this time complete collapse of the lung was obtained. No sputa.

Epicrisis.

The case gives a typical picture of a certain kind of apex-adhesion, of which the author has treated eight. The technique is difficult and the operation risky. This case also proves how difficult it is during the process of operation to judge how far the cauterization has progressed. The very favourable clinical result, without any disturbing influence due to the pleurisy getting worse, is in a high degree noteworthy.

Case 133, Mrs. I.M.L., aged 40. Husband died of pulmonary tuberculosis. Ten children, one treated in the surgical division for tuberculous knee. Quite well till 1913, when she developed fibrinous pleurisy, lasting for seven weeks. Similar condition 1917. This year tuberculosis in lung was diagnosed. Seven months at sanatorium. After that looked after herself at home, felt well and carried out her duties.

At the end of October, 1924, caught a chill, with raised temperature and cough, but improved somewhat during the following weeks. The last month marked emaciation and poor appetite. *Condition* November 29, 1924.—General condition bad. Ordinary frame of body. Superficial fat loose and reduced in amount. Muscles average.

On examination of the lungs one finds on the left side extensive and partly recent tuberculous changes with cavity formations, and on the right side older changes in the upper third. Nothing abnormal found in other organs.

X-ray examination January 8, 1925.—Left-sided pneumothorax. The lower lobe fairly well collapsed at the base. The apex seems to be drawn out towards the lateral posterior thoracic wall by a thin membranous adhesion. At the attachment of this adhesion to the lung there is a cavity, in size nearly as large as a walnut. The apex of the upper lobe is equally prevented from collapsing by several fairly thick strings of adhesions. A thick adhesion is seen in the first interspace, one behind the upper part of the first rib in front and one bundle of adhesions from the lung apex towards the supraclavicular fossa. (Fig. 5.)

January 24.—On thoracoscopy one found a membranous adhesion situated far backwards, its lower edge terminating just above the seat of insertion of the thoracoscopic needle and then continuing forwards. The upper border could not be seen. The cauterization was begun at the lower edge and was

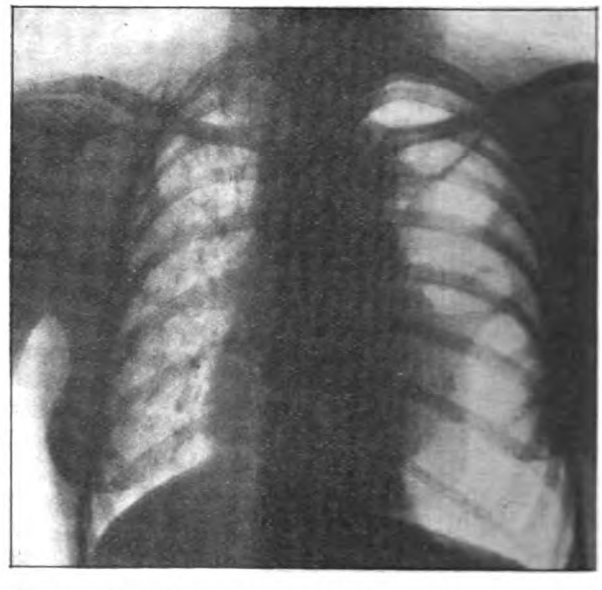

FIG. 5.—Case 133. A string-shaped adhesion obliquely upwards and outwards immediately below the clavicle and one less defined in a straight outward direction. Opposite the middle of the latter a lung-cavity as large as a walnut. In this case, however, there was only one continuous membranous adhesion, extending from the middle of the lung right up to the string-shaped adhesion seen uppermost.

continued for about 15 cm. straight upwards. This adhesion reached a thickness of, at an average, 1 cm.—in several places, however, extending to several centimetres—and was fairly fibrous in structure. Moderate pain. No bleeding.

X-ray examination January 28, 1925.—The left lung now well collapsed. No visible remains of adhesions. Exudate in the sinus. (Fig. 6.)

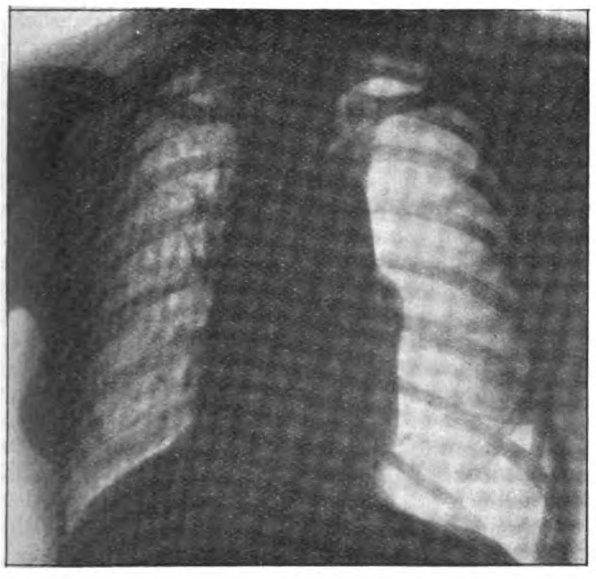

FIG. 6.—The appearance of the lung a few days after the cauterization.

X-ray examination February 17, 1925.—Left lung still well collapsed. No exudate since March 10; sputum: no tubercle bacilli. Discharged April 24 for further treatment at sanatorium.

Comments.

It is of interest to note in this case that, whereas numerous string-like and membrane-like adhesions were found laterally and in the apical region at the X-ray examination, only one large, membranous adhesion was found at the operation with numerous strengthening bands which had simulated free, string-like adhesions in the X-ray picture. The cauterization was comparatively easy and most effective in bringing about collapse of the lung.

"SIMIAN JOURNALISM."

By Sir RONALD ROSS, K.C.B., K.C.M.G., F.R.S.

THE editor has asked me for my remarks on a book called "Microbe Hunters" which has recently been published in America and is said to be by one Paul de Kruif, whose name is entirely unknown to me. It is evidently meant to be a popular history of some discoveries in medical bacteriology and protozoology, that is, a book for the delectation of those who are ignorant of these subjects. An American once said to me, that of all low-class journalism American low-class journalism probably sinks the lowest. Abhorred by respectable Americans the writers make reputations out of vilifying people; and they escape the laws of men just as vermin escape the claws of animals—by their smallness, and, I hear, by the inadequacy of the American laws of libel. Usually, for obvious reasons, such writers persecute only well-known men such as millionaires, politicians and novelists. Unfortunately, it seems that they are now beginning to attack even humble scientists, who are routed out from their obscurity and paraded before an exceptionally ignorant public by men who write books on "Popular Science," without possessing sufficient knowledge of the subjects dealt with, and who do so, not in the interests of truth or of science, but chiefly to support their own existence.

The book under review is written in a "slashing style," but I think without due regard to facts and to the ordinary decencies of journalism. Its first chapters tell us tales of Leeuwenhoek, Spallanzani, Pasteur, Koch and others; most of whom are now dead and cannot reply for themselves. The style is personal, bumptious, and confident; but there are no citations of the literature concerned which would enable readers to verify the statements made. We are given verbatim accounts of conversations which the author could never have listened to and which must, therefore, have been invented out of his own imagination. Although these first chapters are generally laudatory they contain many personal references which their victims would certainly strongly resent if they had still been able to do so.

The later chapters, however, refer to several living persons, including myself, and do so in a manner which in this country would be looked upon as inexcusable. The ninth chapter deals with Bruce

and the tsetse-fly, and it is replete with statements which are misleading and contrary to facts. No credit whatever is given to Low, Christy, Castellani, and Nabarro; on the contrary, some of them are luridly slandered. The following statement is found with regard to the first Sleeping Sickness Commission: "The third member became disgusted with the ignorance and failures of his two colleagues and went off prospecting for rubber." Herewith the answer to this by the third member himself, viz., Dr. Cuthbert Christy:—

"*With regard to Chapter IX of Paul de Kruif's book 'Microbe Hunters,' I beg to emphatically state that it contains statements which are totally erroneous, misleading and some of them quite libellous. As an example I will quote paragraph* 2, *page* 264, *which reads, 'The third member (viz., myself) became disgusted with the ignorance and failures of his two colleagues and went off prospecting for rubber . . . .' This paragraph is absolutely untrue and libellous. It suffices to state that I have always given credit to Castellani for his discovery of the trypanosome as the ætiological agent of sleeping sickness—see, for instance, my letter to the* "Morning Post," *August* 22, 1923. *As regards my abandoning my colleagues, and going off prospecting for rubber, this is entirely libellous. I never abandoned my colleagues and, as a matter of fact, I did not get interested in rubber until* 1906, *which was three years after the labours of the First Sleeping Sickness Commission were completed.*"

Many of the statements found in the same chapter concerning Castellani are equally erroneous and some are pure inventions. It would appear from them that Castellani acquainted Colonel Bruce with his discovery of the trypanosome in the cerebrospinal fluid *en passant* without giving it any importance. Considering that Castellani made certain conditions before acquainting Bruce with his discovery, and that this has been publicly confirmed by Nabarro many times (*British Medical Journal*, October 6, 1917), how can it be said that he attached no importance to his findings and did not see the possible relationship between the trypanosome and sleeping sickness?

There cannot be any doubt that the fundamental discovery in the elucidation of the ætiology of sleeping sickness was Castellani's observations of trypanosomes in the spinal fluid of sleeping sickness patients, and one cannot see why there has been so much discussion on the matter. In the Royal Society's Report No. 8, in the paper by Colonel D. Bruce, Dr. D. Nabarro and E. D. W. Greig, received November 30, 1903, it is stated that "this most interesting discovery of Dr. Castellani's which was due to his introduction of the method of centrifuging the cerebrospinal fluid and his search for his streptococcus, has been of the utmost possible value to the present commission. It put them at once on the right track and led to the rapid and easy elucidation of the ætiology of this hitherto mysterious disease. Without a knowledge of his observation they might have worked for many months in the dark, and in truth, they might have even returned to England still ignorant as to the true cause of the disease." Surely this is very ample acknowledgment.

The tenth chapter is entitled "Ross v. Grassi: Malaria," and appears to me to have been probably written by Grassi himself with a few flaming touches by the author, or else to be compiled almost entirely from information given by the former to the latter, without investigation of the truth, and without citations of the pertinent literature. I am legally advised that many of the passages referring to me are libellous in British law. The author scarcely mentions Laveran, who discovered the malaria parasite in 1880, or King, who was the first to set forth the mosquito theory of malaria as early as 1883. To him, Manson, who added a vitally important item to that theory, was only "an eminent and mildly famous English doctor" who knew little about the subject. "What a pair of men those two were!" On page 282 the author says: "Manson knew so little about mosquitoes that he believed they could only suck blood once in their lives, and Ross talked vaguely about mosquitoes and gnats, not knowing that mosquitoes were gnats"; unfortunately, no one at the time knew better—a fact of which the author seems to be ignorant. He describes my father as "a ferocious-looking, border-fighting English general with belligerent side-whiskers." It appears that my colonel, in 1897, thought me an "insane upstart," that I ill-treated my patients, that I bungled, that I made discoveries which turned out to be no discoveries at all (just as every sound worker does), that I collected malarious Hindoos as a terrier collects rats, and that I loved them if they were full of malaria but detested them when they got better, that I was illogical, that I was anti-scientific, that I wrote shrieking poems, that I tried to stop a cholera epidemic and "did not stop it"—an experience which happens to many; that I wanted to throw my microscope out of the window. "How he fidgetted," says the author. I was a "mad poet." I was "lunatic Ross," I was "wild as the maddest of hatters." My work was done not by me but by one of my native assistants, whom the author calls *Mr.* Mahomed Bux. I fished for trout in India—where they do not exist. I "went wild," and then I "blew up." He sums me up by saying that I failed regarding human malaria. That when I wrote to Manson "the theory is proved," it was not proved, according to this learned author.

It is clear from the author's own writing that he knows little about the subject. On page 282, in describing the parasites of malaria he says that they "turn into little squads of spheres inside the red blood-cells" and then that the spheres "turned suddenly into crescent shapes"! The author evidently does not know what every student of tropical medicine has first to learn in the schools, and yet he presumes to teach others. On page 291, in a completely false statement about me, he confuses the malarial pigment of the parasites with the parasites themselves. If I were to expose and criticize every false or inaccurate statement in his 20 pages about

me I should have to write at equal length. He may have read parts of my "Memoirs" in order to vilify me, but he has not understood them in the least, and he does not mention the Memoirs by name. On the whole I think, from the internal evidence of his book, that he has obtained all that he does *not* know about me from my late ingenious friend, Professor Grassi, who started abusing me in the year 1900 and continued to do so steadily ever since that date until his death last year. I gather the same thing also from the rest of his tenth chapter, which praises that eminent man. He admits on page 298 that it was my work which helped "the learned, the expert, the indignant Battista Grassi to do those clean superb experiments that must end in wiping malaria from the earth. You might know that Giovanni Battista Grassi would be the man to do what Ronald Ross had not quite succeeded in bringing off." So Grassi has been saying all this time! Unfortunately, scarcely any of Grassi's statements (as those of his admirer) are true. Long ago Robert Koch said that "Grassi is a thief and a robber in scientific matters" (my "Memoirs," page 409), and Laveran described his doings as "Mesquins et malhonnêtes (*ibid.*, page 410). The "clean superb experiments" which the author of this book talks about were never made by Grassi. But I am not going to discuss this old matter here. The facts have been exactly stated, with references to all the pertinent literature, in my "Memoirs," and recently in a paper by me in *Science Progress*, No. 78, October, 1925, page 311. Grassi's alleged work on white ants and on eels was done chiefly by S. Calandruccio (see this journal July 1, 1901). The author's statement on page 299, that Grassi had done work on the mosquito theory of malaria before anybody had ever thought of the subject, is completely false. The statement in the author's next paragraph, that in the year 1898, "Grassi, knowing nothing of Ross, never having heard of Ross, went back to malaria again," is also completely false—Grassi mentions my work twice in the first page of the very first paper which he wrote on the subject, and in his next paper he admits having received my Report and one of Manson's articles and specimens from him, and this was before he and his colleagues made any additions at all to our knowledge of the subject. I have exposed this over and over again. The author's statement on page 303, that Grassi declared to the *Lincei* that "it is the anopheles mosquito that carries malaria if any mosquito carries malaria" is utterly apocryphal, as can at once be seen by consulting the original literature, which the author of this book has evidently not done. So also with nearly all of his other statements. The further adventures of Grassi, as related by Mr. Paul de Kruif, remind one of the equally surprising adventures of Sindbad the Sailor or of the late Baron Munchausen—but I really cannot take the trouble to expose the author's inventions in detail. There are also fundamental errors in such other parts of this silly book as I have had the patience to look through, but it is not necessary to mention them.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments**, either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings** per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

THE JOURNAL OF

Tropical Medicine and Hygiene

OCTOBER 1, 1926.

COLOMBIA AND ITS DISEASES.[1]

SINCE the opening of the Panama Canal a few years ago more attention has been directed to the countries of Central America and the adjacent regions, including the Republic of Colombia, formerly known as New Granada, with its capital, Bogota, which occupies the north-western portion of the South American Continent and actually borders on the district of Panama. With an area about thrice that of France or Germany, Colombia has a population of about six million souls.

Lying as it does beneath the Equator, Colombia is, geographically considered, a tropical country, but owing to the configuration of its surface, ranging from the coastal regions and low-lying river basins

[1] "Geografía Médica y Patología de Colombia." Dr. Louis Cuervo Márquez. Bogota and New York: Camacho Roldam y Tamayo. 1915.

to the high mountainous regions of the Andes, it presents a great diversity of climate. Hence five zones have been described as characterizing this variety of climate, namely:

(1) The *tierra ardiente*, limited to a few regions such as the lower parts of the Magdalena River, where the stones are often so hot that they cannot be touched; (2) the *tierra caliente*, the hot region up to an elevation of about 3,000 feet, comprising the plains of the north, west and south-east, and the great river valleys of the Magdalena, Nieta and Putumayo; (3) the *tierra templada*, or temperate zone, at elevations of from 3,000 to 6,500 feet; (4) the *tierra fria*, or cold region, from an elevation of 6,500 to 10,000 feet; and (5) the higher plateaux and mountain slopes. The bulk of the population are to be found in the temperate and cold regions, especially in and around the capital, Bogota, at an altitude of over 5,000 feet.

The tropical low-lying lands, which are unsuitable for the permanent residence of white races, are characterized by the presence of mosquito-transmitted diseases, yellow fever, malaria and filariasis, and in the malarial districts, blackwater fever. Uncinariasis, known also under the names of tun-tun, imbombera, jipatera and tropical anæmia, is the most extensive endemic disease in Colombia. Occurring in the same regions, but much less frequently encountered, is trichocephalosis, infestation with *Trichocephalus trichurus*. Dysentery, both amœbic and bacterial, occurs, and similar symptoms result from infections with the hæmatozoa of paludism, *Balantidium coli*, Trichomonas, Leishmanias, and nematode worms. Spirochætal or recurrent fever, due to *Spirochæti duttoni*, *S. obermeieri*, and other species is encountered in many localities in Colombia. *Ornithodorus moubata and O. turicata* appear to be the transmitting ticks. Leprosy is widely spread throughout the country, occurring at all altitudes and at all temperatures and meteorological conditions. Also widely generalized through Colombia is hypertrophy of the thyroid gland, known as coto, which may exist as the sole glandular manifestation or may co-exist with cretinism.

Although tuberculosis is world-wide in its distribution, and consequently Colombia does not escape its ravages, nevertheless pulmonary tuberculosis has been distinctly rare in Bogota for the last thirty years, and the same may be said of tuberculous meningitis and generalized tuberculosis. No doubt the altitude of Bogota exercises a favourable influence.

Of the eruptive fevers, smallpox presents itself in widespread epidemics, as does measles, with or without whooping cough and scarlet fever, whilst dengue is occasionally encountered in limited areas. Beri-beri is also occasionally met with, and as it does not occur in epidemics, presents great difficulties in diagnosis, having to be differentiated from alcoholic neuritis, paludic cachexia, lumbar myelitis, locomotor ataxia, pernicious anæmia, uncinariasis, interstitial nephritis, and chica intoxication.

A dermatosis practically limited to tropical America, known as carate or pinta, is extremely common in Colombia, where about four per cent. of the population is said to be affected. A patient suffering from this disease is known as a "caratejo." The condition is an inoculable contagious dermatosis produced by the several varieties of the aspergilli and probably other species of fungi, and transmitted by a similium and other insects. Clinically it is characterized by the presence of patches, usually symmetrical, which vary in colour, there being black, blue, violet, red, yellow and white varieties.

The presence of the cutaneous lesion usually produces no repercussion on the general health of the patient, though very exceptionally they are accompanied by fever and all the symptoms of a general infection. The topical application of mercurials to the affected patches constitutes the most effective treatment.

An alcoholic liquid prepared by the fermentation of maize, and known as chica, is a popular beverage throughout the country, and it has been calculated that 250,000 litres of chico are consumed daily in Colombia. Intoxication by chica, accordingly, is extremely common. Insolation, mountain sickness and snake-poisoning are all frequently observed, as would naturally be expected in a country with the geographical position and topographical characters of Colombia.

F. E. T.

Annotations.

The Causation of Malignant Neoplasms (J. Loudon, J. M. McCormack, and N. J. Howard, *Medical Journal and Record*, May 5, 1926).—A similar pleomorphic micro-organism from every type of malignant growth with which the authors have worked has been isolated, including human carcinoma, mouse carcinoma, rat carcinoma, human sarcoma, rat sarcoma (Jensen), and Rous chicken sarcoma No. 1. The life-cycle of this pleomorphic micro-organism consists of three microscopically visible stages and of an ultramicroscopic or filtrable phase. Each of these microscopically visible stages can be grown in pure cultures and subcultures and at will, changed into pure cultures of another stage in its life-cycle. Injections of this micro-organism into animals, with a trace of infusorial earth, produces malignant metastasizing growths. The micro-organism can again be recovered in pure culture from these primary and secondary animal growths. The pleomorphic organism described by Young and Stearn, and by Sturdivant and Stearn appears to be similar to the micro-organism here described. The micrococcus isolated by Nuzum, of Chicago, from carcinomatous tissues and the ultramicroscopic organism described by Gye and Barnard appear to be individual stages in the life-cycle of this micro-organism. The specific factor of Gye contains the living specific micro-organism described herein, though the organism has been attenuated by the chloroform treatment. Human carcinoma has been effectively treated by a serum antitoxin.

Chilomastix Gallinarum, Morphology, Division and Cultivation (W. C. Boeck, *American Journal of Hygiene*, May, 1926).—*Chilomastix gallinarum* occurs in the cæcum of turkeys and chickens. It is readily transferred from one bird to another by the ingestion of material containing the motile or encysted organisms. It possesses three anterior flagella, one cytostomal flagellum, a large cytostome, ventral in position, an anteriorly situated vesicular nucleus, four blepharoplasts and a centrosome. The cysts are similar in shape to those of *Chilomastix mesnili*, but as a rule slender and of smaller dimensions. Division of the motile flagellate is by binary fission. The nucleus passes through the several phases of mitosis. About twelve chromosomes are formed. The parent blepharoplasts divide to form new ones and the new flagella and cytostomal flagellum appear as new outgrowths. The plane of division is morphologically longitudinal. *C. gallinarum* was cultivated for a period of six months in association with *Pygolimax gregariniformis*, an amœba, also from the turkey. The culture media used were either (*a*) Locke solution, 8 parts and human serum 1 part, or (*b*) the L.E.S. medium previously described by Boeck (1924). The parasite, from cultures obtained from the turkey, was transferred to young chicks, either by feeding them with material from cultures or by injecting the material per rectum. *C. gallinarum* differs from the newly-created genus *Tetrachilomastix* (de Fonseca 1916, 1920) inasmuch as it does not possess four free anterior flagella. It differs but slightly from *C. mesnili* from man, but is better accommodated in the genus *Chilomastix* than in the genus *Tetrachilomastix*.

Biological Studies on the Life-Cycle in the Genus Strongyloides Grassi, 1879 (J. H. Sandground, *American Journal of Hygiene*, May, 1926).—A review has been made of the literature on the genus *Strongyloides* and apparently there is nothing known definitely about the underlying causes which determine the alternative modes of development that occur in a number of species of this parasite. The theories that were advanced by Leichtenstern and Darling to explain the phenomenon are found to be either insufficient or entirely inadmissible on further investigation. The belief that the direct mode of development is restricted to infections contracted in the temperate zones and that infections contracted in the tropics show only the indirect or heterogenic mode of development, which formed one of the main foundation-stones for Leichtenstern's hypothesis, is found to be untrue. The usual method of demonstrating the mode of development by the direct examination of small fæcal cultures is unreliable. The examination of cultures of larger amounts of material, using the Baermann isolation technique, reveals the fact that in a large proportion of infections, with various species of the parasite, both modes of development co-exist. It is further shown that by following infections over a considerable time the quantitative relationship between direct and indirect development is subject to constant changes. Infections of certain abnormal hosts lead to changes in the life-cycle, and the suggestion is made that direct development in certain species originally arose following the introduction of the more primitive heterogenic parasite into new species of hosts. The parasitic female of *Strongyloides* is at present held to be parthenogenetic; a cytological study of the gonads indicates that it is really hermaphrodite. This furnishes the basis for a theory that the direction of development is determined by the chromosomal constitution of the eggs, subsequent to fertilization, and that the sex of the rhabditiform generation is determined according to whether the eggs are fertilized by sperm bearing or not bearing a heterochromosome.

Current Literature.

INDIAN MEDICAL GAZETTE.
May, 1926.

Some Factors Affecting the Propagation of Hookworm Infections in the Asansol Mining Settlement, with Special Reference to the Part Played by Cockroaches in Mines (A. C. Chandler).—Surface infestation of the soil with hookworm larvæ is practically entirely stopped for about six months of the year, due to desiccation. In consequence of this break in the continuity of re-infections, hookworm infection is relatively very light in the agricultural villages of the Asansol Mining Settlement, since annually about 60 per cent. of the infection acquired during the favourable monsoon period is lost before re-infection begins again. This lessens the degree of soil infestation at the beginning of each successive favourable season, and thus the infection is kept down to a low level, in spite of defæcation habits which would otherwise favour a high degree of infection.

In the mines disused galleries, especially at the sides of streams, are used as defæcation sites. Conditions of temperature and humidity are highly favourable for the development of hookworm larvæ, but in spite of the fact that there is no desiccation, no activity of Scarabæid beetles, and no domestic animals to feed on the fæces, the stools rapidly disappear, being eaten up by cockroaches. It has been shown that when worm eggs in fæces are eaten by roaches only a few pass through in viable condition, the rest being destroyed by the grinding organs in the proventriculus. Only where numerous stools are daily deposited in a small area are any traces of old stools to be found. Roaches, therefore, play an important part in the control of hookworm infection in mines, and should be encouraged by trapping rats and mice, which prey on them. Only in stools collected in a much used place where the activities of the roaches could not keep pace with the deposition of fresh stools, was a relatively high number of hookworm eggs found. The average eggs per gramme of fæces of these stools were over six times as great as in those found in

scattered stools in the mine, and nearly five times as great as the average eggs per gramme of 75 people living in the coolie lines on the surface.

Variations in the Potency of Digitalis Preparations in the Tropics (II) (R. N. Chopra and P. De).—Last year the authors published a paper pointing out that clinical and biological observations and chemical assays of tinctures of digitalis show that they undergo deterioration rapidly in a warm climate such as that of India. They also showed that tinctures freshly prepared from *Digitalis purpurae* leaf grown in Kashmir, Northern Himalayas, were quite active; but, unfortunately, digitalis is not grown on a large scale in Kashmir. The therapeutic activity of the digitalis grown in Nilgiris is not great. It is grown on a commercial scale at Mungpoo, Eastern Himalayas, and when assayed biologically, different specimens show marked variations in their activity. These variations are probably due to the methods of drying and storing adopted. The outcome of this is that the practitioner does not know what is the strength of the preparation he is administering and is therefore faced with much uncertainty as regards the dosage he should employ and the therapeutic effects he may expect to obtain. Parke, Davis and Co. have imported into India a very powerful tincture, the strength of which is 50 per cent. greater than that of the ordinary tincture of digitalis. It is known as *Digifortis*. This preparation is free from fat, is sold in convenient one-ounce bottles and is further protected from oxidation by the use of carbon dioxide. It should not be used after twelve months after the date of manufacture, which is marked on the bottle. The dose advised by the makers is 8 minims, or 0·5 c.c., but the authors have given 30 minims diluted with a little water, on an empty stomach, without any discomfort to the patient or untoward effects. This preparation also gives good results in cases of heart failure with and without auricular fibrillation. The keeping properties of digifortis have also been tested and have been found excellent.

The Treatment of Syphilis by Benzo-bismuth (S. B. Surti).—Benzo-bismuth has given satisfactory results in the treatment of syphilis in its various stages, but its use is not to be advocated in cases complicated with either gonorrhœa or leprosy. In order to bring about a complete cure from a serological point of view and to maintain complete immunity from the disease, the directions accompanying each box of ampoules should be carefully followed. The advantages of this preparation are the following: (1) The small quantity that is injected not exceeding 1·5 c.c. (2) The ease with which the drug is administered, either intramuscularly or subcutaneously. (3) The painlessness after injection. (4) The uniformity of dosage. (5) The comparative cheapness. (6) No liability to toxic symptoms. (7) Complete solubility of the drug in a watery medium without leaving any particles in suspension.

External Medication in Leprosy (E. Muir).—Leprosy lesions are divided into three classes: (1) Lesions, one or more in number, spreading radially from the centres of infection. (2) Lesions, having the nature of a scar, left by the coalescence of the spreading areas. This character of a scar is not always complete, as the infection may spread from the more superficial layers of the corium, which are first affected, to the deeper layers. Nodulation may be superimposed on such lesions when conditions favour multiplication of bacilli in them. (3) Glove-trophic type, due to the contraction of the newly-formed fibrous tissue around the axis cylinders in the long nerve trunks. Treatment of leprosy is also divided into three divisions: (*a*) means which will cause improvement of the general health of the patient; (*b*) special remedies which may be given by the mouth or by injection; (*c*) external medication. The author has given his attention chiefly to the latter. He gives details of treatment by caustics and surgical treatment of nodules and redundant skin.

Some Observations on the Blood-Sugar after Treatment with Insulin in Diabetes (L. Ghoshal).—The summary of these investigations is as follows: The blood-sugar is higher than what is generally seen by the Folin Wu method, when it is done by the pancreatin and Folin Wu method combined. This excess of sugar is the combined sugar which is not easily breakable. The severity of diabetes depends on the amount of the combined sugar; the less the combined sugar the more severe the case and *vice versa*. Insulin treatment increases the combining power of the blood and thereby diminishes the sugar. It is possible that in this way it prevents the breaking down of fat and thereby prevents acidiosis.

Reviews.

"Protozoology." By Dr. C. M. Wenyon. Baillière, Tindall and Cox. Price 48s. net.

Two Questions of Priority.

This fine work of two volumes and no less than 1563 pages, besides prefatory matter, deserves a close review—which I, for one, am hoping to be able to give or obtain for it; but as I am shortly proceeding to India and the Federated Malay States, I may not have time to do justice to it before my departure; there are, however, two small points of priority in it which should be touched upon at once.

Questions of priority are always thorns in the flesh to those unfortunate people who feel themselves impelled to write textbooks. However just and accurate they endeavour to be they are open to attack by both parties who may be disputing any given question; and as the literature is sometimes very involved, they do not always have a happy time of it—just like those good people who attempt to settle family disputes. I have pity for Dr. Wenyon in this respect; but must confess that

so far as my knowledge goes, he has done ample justice to the utmost of his ability; though, with so much matter to survey, histories of discoveries are apt to be pushed into corners, especially in a book which is both zoological and medical. I think, however, that it may be useful to add the following notes to his, namely, on the subjects of (1) *Leishmania*, and (2) the very old malaria-mosquito discussion.

His principal historical notes on *Leishmania* will be found on page 397. They are perhaps too short when we consider the interest of the theme. The leading papers were published in 1903 and are correctly recorded. Leishman's paper of May 30, 1903, was certainly the first which accurately described the Leishman-Donovan bodies; but he had found them in only one case, in 1900, not "in cases," as Wenyon states. It is not quite clearly set forth in Wenyon's book that Leishman thought they were trypanosomes which had degenerated in dead tissue, although (as I said at the time) the absence of any stained flagella might have warned him against such a hypothesis. It was really the work of C. Donovan, in Madras, which led to the discovery that Leishman's parasites were quite new ones, and were not trypanosomes at all. He sent specimens to Dr. Laveran and to myself in the same year, and when we saw them we at once and simultaneously verified his supposition that we had a new organism to deal with. My first paper was *sent* to the *British Medical Journal* on October 24, 1903, but did not *appear* until November 14 (see *ibid.*, November 21, 1903, page 1359, for an editorial verification of that former date). In the meantime I had written to Laveran and told him of the discovery of the new parasite. He immediately informed me that he had come to the same conclusion; and his paper actually appeared in the *Bulletin de l'Académie de Médicine*, November 3, 1903. In this he suggested the specific name *Piroplasma donovani*. In a second paper, of November 28, I questioned this generic classification and, while accepting Laveran's specific name, proposed a new genus, *Leishmania*, which has now been adopted. Donovan's first observation of the parasites was made on April 9, 1903, and was quite independent of Leishman's observation, which had not then been published, and he deserved very great credit in the discovery. Leishman had observed the characteristic of the two associated chromatin bodies in the parasites, though his photographs did not show this. Donovan also had noted the same double nucleus; and it was his observations, carried out on a number of cases, which proved that we had a new parasite to deal with. In my opinion the discovery should, therefore, be attributed to both these distinguished observers. See also my paper with a coloured plate in the *Thompson Yates Laboratory Reports*, Vol. V, Part 2, 1903. F. Marchand had also seen the bodies and sent me a specimen of them later; but he thought that they were fragments of nuclear matter, and did not describe the double nucleus. J. W. Wright also found the bodies independently about the same time in a case of oriental sore and clearly described the double nucleus and named the parasites; but his paper was not published until December, 1903 (*Journ. Medical Research*, x, 472).

On pages 909-911 of his book Wenyon gives a very fair account of the *malaria-mosquito discovery* made in 1897-98. I see that in his bibliography, page 1485, he says that my *Report on the Cultivation of Proteosoma* was dated May 21 (which is quite correct) but that it was "issued October, 1898." As a matter of fact that was the date of the *official* issue which, as everyone knows, is often very different from the real date of issue. This was June, 1898, when thirty or forty advance copies of the work were sent from India to Europe, America and elsewhere—see my "Memoirs" (Murray, 1923), pages 288 and 332. Manson received a number of these copies and forwarded some of them to Italy, presumably in July, at the end of which month he gave a full address to the British Medical Association at Edinburgh, largely based on my report, regarding the whole of my researches, including the infection of healthy birds in July, notified to him by telegram. This address was printed with my drawings in the JOURNAL OF TROPICAL MEDICINE for August, in the *Lancet*, August 20, and in the *British Medical Journal*, September 24, 1898. My own report, already mentioned, contained full details of the new and difficult technique, with drawings of the mosquito-cycle of *Proteosoma*, and must have reached far and wide about the same time as Manson's address. In fact, no scientific discovery could have been more fully published than was this one during August and September, 1898. I may add that two papers by me and one by Manson, all announcing my work, but less completely, had already appeared, and that yet one more on the infection of birds appeared in October. These papers of ours hold complete priority in date of publication.

Yet Dr. Wenyon, with true scientific caution, dares only to remark, on page 910 of his book, that "Grassi may have been, and probably was, influenced and guided to some extent by what he had heard of Ross's discoveries." It is not a matter of mere probability, but of complete certainty, that Grassi's work was not only "influenced and guided to some extent" by mine, but was based entirely upon it, and that Grassi had not only heard of my discoveries, but had fully studied the literature. This is proved, apart from other evidence, by their own published admissions weeks before Bastianelli, Bignami and Grassi reached any real result at all—which was not until November, 1898, at earliest. In his very first publication of 1898, dated September 29 (*Policlinico*, October 1), G. B. Grassi refers to my work in the third and the sixth paragraphs of his article. In his next paper on the subject (*Lincei*, Vol. VII, page 235, seduta del 6 novembre 1898), Grassi mentions Manson and me several times and admits having received "alla fine di settembre," not only Manson's address to the British Medical Association, but also some of my proteosoma mosquitoes through

Manson from India, and a "Memoria del Ross," which could have only been my *Report on the Cultivation of Proteosoma* itself, forwarded to him by Manson. The first Italian result of any value at all was achieved by A. Bignami, in the experimental infection of the man Sola, which was proved on November 3 (but was only a repetition of my previous infection of birds in July). This was published by Bignami in his first paper of 1898 (*Bull. R. Acad. Med. d. Roma.*, November 15), of which a translation appeared in the *Lancet*, December 3 and 10; and in this paper (page 1462) Bignami not only admits receipt of my Report, but discusses the work of Manson and myself at length. The very first alleged observation of the mosquito-cycle of any of the malaria parasites by these workers was not recorded until December 4 (*Atti d. R. Accad. d. Lincei*, Vol. VII, page 313, inviata il 28 novembre, 1898). In this paper, Bastianelli, Bignami and Grassi not only refer to my original discovery of August 20 and 21, 1897, concerned with human malaria in "dappled-winged" mosquitoes, and published a year previously (December 18, 1897), but express the view that these mosquitoes were actually *Anopheles claviger*, and mention several times me and my work on *Proteosoma*, which had been fully published by Manson and myself more than four months previously. Dr. Wenyon mentions only one of these four papers in his bibliography and appears not to have read them. I shall be glad to show original copies of all of them to him or to anyone else who desires to see them.

If he requires further evidence that these observers were quite familiar with my work he will find it in my "Memoirs" (which also he does not mention in his bibliography), in the letters to me from Dr. Edmonston Charles from Rome, from November 4 to December 2 (pages 336 to 347 of my "Memoirs"). Charles visited Grassi and Bignami and described all that they were doing at the time. On November 4 he writes: "It has been a cause of surprise to me how very closely they have followed all that you have done, and how fluently they talk regarding the details of your work." On November 25, he wrote again to me: "I went to Professor Grassi's laboratory and showed him one of your preparations (third day, from the sparrow), showing pigments, &c., in the walls of the mosquito's stomach." This specimen had been lent to him for this very purpose by Manson. Then Charles adds: "He (Grassi) had before him *The British Medical Journal* with your paper of the 18th December, 1897, and seemed perfectly satisfied that your description of the mosquito referred to the *Anopheles claviger*." What more evidence is required? I shall be glad to show the originals of these letters also to anyone. It was not until a year and a half later that Grassi claimed in his "Studi di uno Zoologo" to have made the whole discovery "indipendentemente da Ross."

It is an obvious rule that priority in the discovery of the life-cycle of any biological group belongs to him who first demonstrates that life-cycle in any species of the group—often a very difficult task. It is absurd to pretend that those who afterwards find the same life-cycle in other members of the same group—generally an easy task—deserve an equal credit.

The life-cycle of the *Plasmodiidæ* in mosquitoes was discovered by Manson and myself, first partly in the case of *P. falciparum* in dappled-winged mosquitoes (obviously *Anopheles*) in 1897, and then completely in the case of *P. relictum* (*Proteosoma*) in *Culex fatigans* next year. The priority belongs to us—not to those who merely extended our results, months afterwards, by finding precisely the same life-cycle for other species of the group. I could easily have done the same thing but for the two interruptions which the Indian authorities imposed upon me just when I was able to undertake the work. I *did* do the same thing some months later in Sierra Leone, within a few weeks.

Unlike me, Bastianelli, Bignami and Grassi were able to name their mosquitoes owing to Ficalbi's recent work on Italian mosquitoes. They were able to stain their specimens by the Romanowsky method: while I was always too busy with my fundamental differential experiments which established the theory to attempt such details. It was owing to A. Bignami that *P. vivax* was also found to develop in *Anopheles*; and he deserves by far the chief credit in all the Italian work. Otherwise that work was secondary in nature and was simply on a par with exactly similar work which has now been carried out almost everywhere.

The discovery of conjugation in *Plasmodia* was made by W. G. MacCallum in 1897, quite independently of me, and enabled Manson to explain my initial results. It need not be discussed here; but it added, of course, a fundamental item to the general theory.

I must repeat that my work was done, not in the interests of general parasitology, but solely in order to diminish human sickness and mortality. It could not possibly have been carried further than it was in the short time allotted to me up to August 13, 1898, when I was obliged to leave Calcutta in order to investigate kala-azar in Assam.

The fundamental discovery was made, after more than two years' constant failures with many species of Culicines, on August 20, 1897, when I found the "pigmented cells" in the stomach-wall of a "dappled-winged" mosquito, bred from the larva and fed on a case of *Plasmodium falciparum*. This indicated both of the two unknown quantities, namely, the form and position of the parasites in the insect, and the type of mosquito concerned: and all that has been done on the subject since then has been an easy consequence of that fortunate observation. The discovery was fully published, with drawings of the cells and remarks by Manson and others, in the *British Medical Journal* of December 18, 1897, page 1786, nearly a year before Grassi and Bignami obtained definite results; and from that paper alone they, or anyone else, could have readily followed (and did follow) my work.

RONALD ROSS

Original Communication.

OBSERVATIONS ON THE PATHOLOGY OF THE CENTRAL NERVOUS SYSTEM IN MALIGNANT TERTIAN MALARIA, WITH REMARKS ON CERTAIN CLINICAL PHENOMENA.

By JOHN GORDON THOMSON, M.A., M.B., Ch.B.,
Director, Department of Protozoology,
AND
S. ANNECKE, M.A., M.B., D.P.H.,
Demonstrator, Department of Protozoology,
London School of Hygiene and Tropical Medicine.

INTRODUCTORY.

ON a visit to England Professor Carly Seyfarth drew attention to certain interesting histo-pathological changes of common occurrence in the central nervous systems of cases which had died as a result of comatose malaria.

The observations of Margulis (1914), Dürck (1917), Fränkel (1917), Oesterlin (1920), Weingartner (1920), Marinescu (1920), Obregia and Popea (1924), Freifeld (1924), Dürck (1925), and Seyfarth (1926), have demonstrated that, in a large number of cases which have succumbed as the result of an attack of pernicious malaria, nodules may occur in the subcortical area of the cerebrum and more rarely in the cerebellum, which Dürck and Seyfarth consider may be of the nature of true granulomata. These characteristic lesions of the central nervous system would seem to place malaria amongst that group of diseases associated with multiple sclerosis. As little attention has been directed to the study of these by English workers, an examination of a considerable amount of brain material in our possession was undertaken. The possible far-reaching consequences of such lesions on the mental attitude and general nervous system of patients who have suffered from infection with *Plasmodium falciparum*, would seem to merit further careful clinical observation, especially in cases associated with previous attacks of coma.

THE PATHOLOGY OF THE CENTRAL NERVOUS SYSTEM WITH SPECIAL REFERENCE TO THE SO-CALLED "MALARIAL NODULES" OR "MALARIAL GRANULOMATA."

An examination of the literature of the histopathology of the central nervous system in malaria points to the fact that most of these observations have been conducted on cases which have succumbed to coma due to severe infections with *P. falciparum*. Post-mortem examination of malarial tissue in the pathological laboratory is often a very rapid event, consisting of the taking of a few brain smears or the removal of random samples of cortical tissue for diagnostic purposes. There is need for a more thorough and systematic examination of the various areas of the cerebrum, cerebellum, pons, medulla, spinal cord, &c., if the knowledge of the various changes and lesions in the central nervous system associated with malaria is to be increased.

Early observations on the pathology of the brain in malaria were made by the Italian workers, a good account of which is given in the monographs of Marchiafava and Bignami (1894) and Mannaberg (1894). The treatise of Laveran (1907) added further observations on the subject, and more recently Cerletti (1909) and Lafora (1912) have given details on certain cell changes.

Macroscopically in section the brain substance has a distinct smoky grey to brownish appearance due to the numerous pigmented parasites. Œdema, hyperæmia, and punctiform hæmorrhages of varying gradation are usually visible to the naked eye in the white matter. The meninges are slightly infiltrated, the vessels congested, and actual hæmorrhages may occur. Monier-Vinard, Paisseau and Lemaire (1916) have described the cellular reaction in these and found it to be chiefly lymphocytic in type. Polymorphonuclears are rare, but mononuclears and endothelial cells occur in increased numbers. In some cases under examination the subarachnoid connective tissue showed a diffuse small-celled infiltration which was chiefly perivascular, but also diffuse, that is, not confined to the perivascular spaces. Laveran described leptomeningitis, and Dürck has confirmed this. The most obvious microscopical feature in the cortical and subcortical areas of the cerebrum and cerebellum is the more or less complete blockage of the brain capillaries with parasitized red cells, which, owing to their tendency to clump together and stick to the endothelial cells at the periphery of the vessel, cause œdema, stasis, thrombosis and punctiform hæmorrhages. The capillary vessels seem to be increased in number, but this is possibly more apparent than real, since, owing to their engorgement, they are rendered more obvious. The endothelial cells lining the vessels are actively phagocytic; their protoplasm tends to swell and become vacuolated and contain substances of a fatty or lipoid nature. These cells become detached from the vessel walls in large numbers and may be seen in acute pernicious malaria circulating in the peripheral blood in various stages of degeneration. Further, they may aid very materially in the formation of thrombi in the minute capillaries. Lafora (1912) noted that the adventitial cells appeared to be greatly degenerated and pyknosed. Further, these cells showed a tendency to detach themselves and to penetrate the nerve tissues forming the so-called "Stäbchenzellen." In the adventitial spaces lymphocytes may be seen, and, according to Cerletti (1909), plasma cells sometimes occur in the lumen of the vessels and in the lymphatic spaces. The perivascular lymphatic spaces, according to Freifeld (1924), are more distinct, due to œdema, and he thinks these are the transition stage of a pericellular infiltration. Several authors state there may be extensive degeneration of the ganglion cells (Lafora, 1912; Dürck, 1926), which often show extensive chromatolysis with swelling and vacuo-

lation of the cytoplasm, loss of Nissl granules accompanied with degeneration of the medullated fibres. Lafora records the presence in the grey matter, and still more abundantly in the white matter, of astrocytes, large cells with thick insertion feet and showing very marked cystic degeneration of the protoplasm. Such cells are frequently described in other acute processes, e.g., paresis.

Punctiform hæmorrhages occur most commonly in the subcortical area, but also are found, though less frequently, in the cortex. It is a curious feature that the red cells in these areas seldom show parasites, although the neighbouring capillaries are packed with parasitized cells. Finally, we have the description of the so-called " malarial nodules " or " malarial granulomata " studied by Margulis (1914), and the other observers.

Various portions of the cerebrum of twelve cases of malignant tertian malaria, in which death was directly due to coma, were examined by us, and, in two of these, cerebellar tissue was also studied. Our object was to establish the frequency of these so-called " malarial nodules " or " malarial granulomata " cited by various German workers. In three, these lesions occurred in the subcortical area of the cerebrum, and in one they were also found in the cerebellum. One brain in particular, from which the photomicrographs appended in Plates I and II were taken, showed numerous lesions associated with punctiform hæmorrhages. These appear to have been noted first by Margulis (1914), and his observations were confirmed by Dürck (1917) and others. The most typical of these lesions in the present series occurred in the subcortical area of the cerebrum immediately subjacent to the deepest layer of the cortex; they were closely associated with the presence of numerous punctiform hæmorrhages in the subcortical regions of both cerebrum and cerebellum (*vide* Plate I, figs. 1 and 5, and Plate II, fig. 2).

In a characteristic nodule (*vide* Plate 1, figs. 2 and 3, which are taken at a magnification of approximately 200 diameters, and Plate II, figs. 3 and 4, at a higher magnification, namely, 500) there is a central capillary containing parasites surrounded by a perivascular necrotic area. Around this is a circle of proliferating glial cells, and, forming a ring around the glial cells and intermingling with them, are numerous red blood-cells with no parasites. Margulis (1914) noted the zone of extravasated red blood-corpuscles surrounding the perivascular necrotic area. The radially placed proliferating glial cells may show mitotic figures, and their nuclei are often bayonet-shaped, the whole arrangement of a typical nodule suggesting an aster. Margulis attributes these nodules to stasis and thrombosis in the neighbouring capillaries, and draws an analogy to the sclerosis which occurs in other organs due to attempted repair. He also found them in the optic thalamus. Dürck (1917 and 1925) has carefully studied and illustrated the pathology of these lesions. He considers the perivascular masses to be a result of the action of the malarial toxins, and that they can be regarded as a defensive inflammatory process. Further, he advances the view that they are comparable to true granulomata, which are capable of producing multiple sclerotic areas. He never failed to find these nodules in pernicious malaria. Changes seen in the brain of typhus cases somewhat suggest the malarial granuloma, but Spielmeyer (1919) has pointed out that the cell masses found in the brain of the former can be differentiated from those of malaria in that there was no necrosis and no radial symmetry of the glial cells. Fränkel (1917) noted nodules in one case, and Oesterlin (1920) in 24 cases found localized glial proliferation four times in the cerebrum, twice in the cerebellum, and once in both cerebrum and cerebellum. The same author describes them once in a case of tertian fever which succumbed to an intercurrent disease, and once in a case of blackwater fever.

Weingartner (1920) gives a good description of these lesions and states that the glial cells obviously proliferate around a previous capillary hæmorrhage—the latter being possibly due to stasis and thrombosis. Dürck, however, found them unassociated with hæmorrhages. Marinescu (1920) noted their occurrence in association with hæmorrhages, and stated they were due to an irritative reaction either from the hæmorrhage or malarial toxins, as nearly all of them were encountered on the course of a vessel.

Obregia and Popea (1924) described them in two cases, and also gave the size of these nodules, 30 to 150 microns in diameter. Freifeld (1924) in Russia reports them in pernicious and also from a case of quartan malaria.

Seyfarth (1926), in his description of the pathology of malaria, gives an excellent account of these nodules, emphasizing the fact that they are capable of producing a multiple sclerotic condition. He further states that, in the recovery of patients with such lesions, the brain can never recover the former quality or functions, and, apart from gross lesions, memory disturbances are marked in quite 50 per cent. of all serious cases.

In the case illustrated the most striking feature was the association of these so-called granulomata with numerous punctiform hæmorrhages. These hæmorrhages also occurred in the cerebellum of the same case, and figure 4, Plate I, shows one into the cortex of the cerebellum; fig. 5 in the same plate shows a hæmorrhage into the subcortical area of the cerebellum, with a commencing necrotic centre unaltered red cells being arranged in a circle around the periphery.

Fig. 1, Plate II, shows the blocking of a capillary in this brain with parasites. There seems undoubtedly to be a relationship between the hæmorrhages and the granulomata—the hæmorrhage being as it were the precursor. Fig. 3, Plate I, shows one of these nodules, and the one on the left of the photograph shows the capillary opening into the region of the lesion, which has already necrosed in the centre. Curiously enough, there are seldom para-

PLATE II. ×500.

To illustrate article, "Observations on the Pathology of the Central Nervous System in Malignant Tertian Malaria, with Remarks on Certain Clinical Phenomena," by JOHN GORDON THOMSON, M.A., M.B., Ch.B., and S. ANNECKE, M.A., M.B., D.P.H.

sites in the extravascular corpuscles which form a ring around the necrotic area. It is difficult to explain the presence of these unaltered red blood-cells forming a ring around the outside of the nodule and intermingling with the circle of glial cells.

Although these so-called granulomata are possibly independent of hæmorrhages (Dürck 1925) and due to continued irritation from toxins, these observations lead us to consider they may frequently result from hæmorrhage. It might be presumed that, as central necrosis progressed in the hæmorrhage, it called forth on the part of the tissue a reaction stimulus, namely, glial proliferation. This would proceed until healing was complete, leaving a scar. Different stages of this process occur in the figures (*vide* Plate I, figs. 1, 2, 3, 4 and 5, and Plate II, figs. 2, 3 and 4). Unaltered red cells can be seen at the periphery intermingling with glial cells, especially in Plate II, figs. 3 and 4, showing the process is incomplete.

Neurological Sequelæ Resulting from Malaria.

The mental manifestations and general nervous symptoms of acute and chronic malaria have received a considerable amount of clinical attention, and, while numerous pathological studies have been made, it cannot in most instances be said that these have been correlated with the clinical observations noted before death.

While malaria, *per se*, can produce protean neurological phenomena, it is evident that many of those quoted were probably influenced by heredity, arteriosclerosis, cardiac disease, syphilis, alcohol, or some other concomitant infection which had been overlooked. Certain neuroses and psychoses may be coincident with an attack of malaria or even precipitated by it, but the primary causal factors may be due to other causes which can only be determined by further observations.

It is impossible to discuss fully in this communication the varied clinical manifestations attributed to malaria of the central nervous system, but, from a study of the pathology of brain lesions associated with coma, this disease in after-life might have far-reaching results.

For convenience in clinical studies of the nervous symptoms encountered it would seem useful to consider them in two groups, namely, those associated with acute malaria, and the various mental and nervous conditions of a more chronic character in patients no longer suffering from acute symptoms. In these two groups there may be an overlapping in that certain symptoms of the first may be carried over and become chronic in the second owing, as has already been indicated, to more or less gross lesions causing permanent damage and imperfect repair. It is this latter condition it is desired to emphasize owing to the pathological observations noted in this paper.

As a result of severe acute malaria the following definite clinical manifestations have been encountered by various authorities: attacks of an apoplectic nature, i.e., sudden unconsciousness with little or no premonitory symptoms, hyperpyrexia, convulsions, epileptiform seizures, uncontrollable sweating, chorea, bulbar paralysis, cerebellar disturbances, hemiplegia and paraplegia; localized nerve lesions confined to definite nerves such as the third or seventh, multiple sclerosis, amaurosis, peripheral neuritis, mental disturbances common in acute malaria such as coma, delirium, violence, aphasia, loss of memory, confusion, depression, excitement with violence or symptoms of insanity such as dementia præcox or delusional insanity, meningeal symptoms.

Although the severe pathological conditions associated with coma due to *Plasmodium falciparum* can produce the protean clinical symptoms encountered, many suggestions have been put forward to explain them, for example, punctiform hæmorrhages, œdema (due to the interference with the capillary circulation), foci of softening in the nervous system due to thrombi, toxins in the blood, alterations in the blood itself, malarial cachexia, focal anæmias produced by interference with the circulation, polyneuritis due to the action of circulating toxins in the peripheral nerves or the œdema of the spinal meninges resulting in a compression of the nerve roots and finally sclerosis of multiple character resulting from the repair of numerous necrotic foci.

As a general rule almost all of the above symptoms associated with acute pernicious malaria quickly respond to treatment, but it would seem that those mental and nervous symptoms of a more chronic character, attributed to previous malaria, require further study by careful clinical observation, correlated with the malarial history. Various degrees of mental impairment such as depression, loss of memory of varying degrees, &c., might conceivably result from the grosser lesions described above.

DESCRIPTION OF PLATE I.

Plate I.—Photomicrographs. Magnification approximately 200.

Fig. 1.—Hæmorrhage into subcortical layer of cerebrum, showing ruptured capillary with extravasation of red blood-cells and very early glial proliferation. This may develop into Fig. 2.

Fig. 2.—This shows typical necrotic area with centrally placed capillary surrounded by area of necrosis; proliferating glial cells intermingled with red blood-cells can be seen around this necrotic area.

Fig. 3.—Two areas of necrosis. Left hand one shows capillary coming into area from periphery (lower edge). Right hand one shows capillary in centre of area.

Fig. 4.—Hæmorrhage into cortex of cerebellum. Capillary traversing picture towards right edge plugged with parasites and pigment.

Fig. 5.—Hæmorrhage into subcortical layer of cerebellum. Central necrotic area surrounded by radially placed proliferating glial cells, interspersed with red blood-corpuscles.

DESCRIPTION OF PLATE II.

Plate II.—Photomicrographs. Magnification approximately 500.

Fig. 1.—Capillary vessel filled with pigmented parasites.

Fig. 2.—Hæmorrhage into subcortical layer of cerebrum showing red blood-corpuscles among which can be seen early proliferating glial cells.

FIG. 3.—Typical so-called granuloma in subcortical layer of cerebrum. Necrotic area with centrally placed capillary filled with parasites and pigment. Endothelial lining of vessel desquamated and shed; area of necrosis surrounded by proliferating glial cells interspersed with red blood-cells.

FIG. 4.—Typical so-called granuloma. Necrotic area in subcortical layer of cerebrum. Centrally placed capillary with area of necrosis surrounding vessel and outside this glial proliferation and red blood-corpuscles.

FURTHER EXPERIMENTS WITH THE GONGYLONEMA OF CATTLE.—II.

By H. A. BAYLIS, M.A., D.Sc.,
A. LESLIE SHEATHER, D.Sc., M.R.C.V.S.,
AND
W. H. ANDREWS, D.Sc., M.R.C.V.S.

(I) INFECTION OF PIGS.

IN a previous paper (1926) we have recorded the negative result of an attempt to infect pigs with the cattle form of *Gongylonema* (generally known as *G. scutatum*, but believed, on morphological grounds, to be identical with the *G. pulchrum* of swine). This result was somewhat surprising, and we thought it desirable to repeat the experiment, which has accordingly now been done, this time with positive results.

On April 14, 1926, two pigs were fed with cockroaches (*Blattella germanica*) which had been experimentally infected with the larvæ of the cattle *Gongylonema*.

One pig, which may be called *A*, received 52 *Blattella* which had been fed with eggs from worms obtained from an experimental calf. Many of these cockroaches were very small, and they included only about 11 full-grown or nearly full-grown specimens. The second pig (*B*) received 28 *Blattella*, mostly full-grown, which had been fed with eggs from worms obtained from two experimental sheep. (The original stock of worms from which both the calf and sheep had been infected previously was derived from cattle in the Trentino, Italy.)

On July 30, 1926 (107 days after the infective feeding), both pigs were killed, and post-mortem examination revealed 14 specimens of *Gongylonema* in the mucous membrane of the mouth and œsophagus of *A*, and 9 specimens in that of the mouth of *B*. The individual worms were distributed as follows:—

Pig	Cheeks and gums	Sides of tongue	Œ-ophagus
A ...	5 ...	6 ...	3
B ...	5 ...	4 ...	nil

All the worms were small, but they appeared to be mature, many of the eggs in the uteri of the females already containing fully-formed embryos. The largest female (in pig *A*) was about 37 mm. long, and the largest male was about 24 mm. The largest female in pig *B* was about 31 mm. long. Although ample time appears to have been allowed for the development of the worms to maturity, these measurements are distinctly below the average for the form ("*G. scutatum*" naturally occurring in ruminants, but are in close agreement with those given by various describers for the supposed distinct species, *G. pulchrum* and *G. ransomi*, found in pigs (see Baylis, 1925). The left spicules of six males measured about 12, 11·9, 12, 9·5 and 10 mm. respectively.

The result of this experiment seems to lend considerable support to the view already expressed by one of us (Baylis, 1925) that the forms known

G. pulchrum, *G. ransomi* and *G. scutatum* are but a single species. It may perhaps be pointed out, further, that specimens of *Gongylonema* hitherto found naturally occurring in pigs appear (like those in the present experiment and like the few examples known to have occurred in man) not uncommonly to have been situated in the mucous membrane of the mouth and tongue rather than in the œsophagus. It is not unusual to find that a somewhat abnormal position is taken up by a parasite when it finds itself in an abnormal host, and correlated with this is the further fact that nematodes, in these circumstances, often fail to attain the size usual in their proper hosts. It may be suggested, therefore, that very possibly both the pig and man are but accidental hosts of the species which normally inhabits the œsophageal lining of ruminants (cattle, sheep, goats, &c.).

(II) Experiments with the Infective Larvæ.

(*a*) *Their Power of Living in Water.*

The life-history of *Gongylonema* involves an insect intermediate host—either one of several dung-feeding beetles or one of several species of cockroaches. In order to become infected, the final host must either swallow the insect containing the infective ("third stage") larvæ, or must come into contact by some means with these larvæ after their liberation from the insect. In all probability the former is, for most animals that harbour *Gongylonema*, the usual means of infection. It is almost certainly so in the case of rats, which will readily, and even eagerly, devour the cockroaches which harbour the larvæ of *Gongylonema neoplasticum*. In a former experiment (see Baylis, Pan and Sambon, 1925) rats were infected with the *Gongylonema* of cattle by administering to them, in water, larvæ dissected out from their intermediate hosts. It is clear, therefore, that it is not essential for the larvæ to be ingested while still contained in their capsules in the insect host, and to be liberated therefrom in the final host's digestive tract. Moreover, larvæ had sometimes been observed to remain alive in water for some hours in the laboratory.

It was thought desirable, therefore, to carry out some experiments in order to determine (*a*) whether the larvæ would actively emerge from their insect hosts if these happened to fall into the water, and (*b*) if so, how long the larvæ could survive in water.

Experiment I.—Accordingly, 12 cockroaches (*Blattella germanica*), from a batch previously infected by feeding with eggs of the cattle *Gongylonema*, were killed by one of us (H.A.B.) with as little damage as possible, by pinching the thorax, and placed in a small dish of tap-water at room temperature (April 6, 1926). On the next day (24 hours after the beginning of the experiment), no *Gongylonema* larvæ were found free in the water, but two of the insects were dissected, and one of them was found to be very heavily infected. The remaining 10 cockroaches were left in the water, and on the following day five *Gongylonema* larvæ were found free and alive in the water. The cockroaches were by this time decomposing, and on this day and each subsequent day they were transferred to fresh water, but otherwise the natural processes of decomposition and disintegration were not interfered with. The larvæ which had emerged each day were collected and placed in a separate small vessel of water, and kept by themselves at room temperature.

On the third day, the first five larvæ were still alive, and three more had emerged from the cockroaches. On the fourth day, two more were found. Living and active larvæ continued to emerge from the disintegrating bodies of the cockroaches in this way until the seventeenth day of the experiment (April 22). After this date, dead larvæ continued to appear for some days in the water containing the cockroaches, but no more living larvæ were observed. (Owing to the illness of the investigator, continuous observation ceased after April 26.) In all, at least 49 living larvæ emerged from the 10 cockroaches—an average of nearly five per cockroach—in a period of 17 days. These larvæ, transferred to clean water, remained alive for periods varying from four to eleven days. An interesting point is, that the length of life of the larvæ after emergence did not appear to be affected by the length of time previously spent in the submerged bodies of the dead cockroaches. Those which emerged towards the end of the period of the experiment lived, on an average, as long as those which had emerged at least 11 days earlier.

Experiment II.—A parallel experiment, somewhat modified, was made by one of us (A.L.S.) in the following way:—

On May 4, ten specimens of *Blattella*, previously infected by feeding with the eggs of the cattle *Gongylonema*, were killed by carefully pinching the thorax with forceps, and placed in a Petri dish of water. On the following day (as in experiment I) no larvæ were found in the dish. It was thought that a possible explanation of this was that in killing the cockroaches no damage had been done to the abdomen. The insects were therefore divided into two batches of five each, which were placed in separate dishes, this time in normal saline solution. One batch was left as before, while the abdominal walls of the other batch were torn with a needle. This was done at about 11 a.m. By 2 p.m. on the same day, three living larvæ were found to have emerged from the "torn" cockroaches, and by 4 p.m. three more. These were collected and placed in a watch-glass containing normal saline solution.

On the third day (May 6) nine more larvæ were found in the dish of "torn" cockroaches, but none in the "untorn" dish. Three cockroaches from the "untorn" batch were now removed to another dish and their abdomens were torn. One larva emerged within 15 minutes at room temperature. Larvæ being required for another experiment, the remaining two "untorn" cockroaches were now torn and placed with their original companions. There were thus again two dishes of saline, each containing five cockroaches. The insects were now

broken up, each into three or four pieces, and the dishes were placed in an incubator at body temperature. This, it had already been found, caused a great increase in the activity of the larvæ. The dishes were allowed to stand for half an hour in the incubator in order to become warm, and were then taken out in turn at intervals and searched. The larvæ were collected and the dishes returned to the incubator. After each dish had been searched three times no more larvæ could be found. The total number collected from the two dishes was 114—an average of about 11 larvæ per cockroach.

It appears from the results of experiments (I) and (II) that the larvæ may be unable to escape from the abdomen of the host until some disintegration of its wall has taken place. This disintegration begins to take place naturally by the second day at room temperature in tap-water, but is possibly somewhat retarded by the use of normal saline solution. The emergence of the larvæ is greatly hastened by raising the temperature to 37° C., doubtless as a result of their increased activity.

From these experiments it is evident that drinking water must be taken into consideration as a possible source of infection with *Gongylonema*, not only for animals but for man. Should the intermediate hosts fall into a suitable water supply they will, sooner or later, liberate the contained larvæ, which may then be ingested by animals or human beings drinking the water. One fact, however, renders this mode of infection somewhat unlikely to be common. The larvæ, when they find themselves in water, make no attempt to swim or float, but sink at once to the bottom, where they remain, at ordinary temperatures, usually in a closely coiled and sluggish condition. The water, therefore, must probably be very shallow for the worms to be easily taken up with it.

(*b*) *The Question of Skin-penetration*

There remained the possibility that ingestion by the mouth might not be the only way of acquiring infection through contaminated water. It was possible that the larvæ might have the power of penetrating the skin or mucous membranes of animals when in contact with the water, as is known to be the case with certain nematodes of other families. Accordingly, the following experiments were made.

(1) Eleven third-stage larvæ, obtained by dissection from experimentally-infected *Blattella*, were placed in a drop of water on a piece of shaved and freshly excised skin from the abdomen of a rat. This had been stretched over a hole in a piece of cork and floated on normal salt solution at a temperature of 37° C. (Goodey's method). This was done at about 12 noon, and the larvæ were watched at intervals. They became very active at the raised temperature, but appeared to make no attempt to penetrate the skin. At 2.30 p.m. all the eleven larvæ were recovered from the surface, none having penetrated into the skin.

(2) Two larvæ were placed, under similar conditions, in water on the inner surface of a fresh piece of œsophagus from a rat. They were kept under observation for about half an hour, but were not seen to make any attempt at penetration.

(3) Five larvæ were similarly placed on the lining of the cardiac (stratified epithelium) portion of a rat's stomach. Kept under observation for about an hour, they appeared to make no attempt at penetration. As often as the drop of water began to dry up, they became very sluggish, reviving promptly when more water was added. This appears to indicate that the reason for their non-penetration is not (as Goodey has found to be the case with hookworm larvæ) that they require a very shallow film of water in order to obtain the necessary purchase.

(4) Five larvæ (collected overnight and kept in water at room temperature) were placed (using the same technique as indicated above) in water on a piece of the lining of a fresh sheep's œsophagus. This œsophagus had been conveyed in normal saline straight from the slaughter-house to the laboratory. Four more larvæ from the same batch were similarly placed on a piece of the lining of another sheep's œsophagus, equally fresh, but kept without saline. In both cases the larvæ were kept under observation for over an hour, but showed no disposition to penetrate the epithelium.

These experiments, though necessarily carried out on a small scale and under artificial conditions, seem to afford some evidence that the larvæ of *Gongylonema*, at least when in water, do not possess the instinct or the power of directly penetrating the skin or the mucous membrane of the upper portion of the digestive tract of their final hosts.

(*c*) *The Question of the Route of Migration within the Body of the Final Host.*

It is a question of considerable interest how the larvæ of *Gongylonema*, once having entered the body of the final host, come to take up the position in which the adult worms are usually found: namely, in the thickness of the epithelium of the œsophagus, stomach or buccal cavity. Upon this question we have been able to throw no important light, our experiments having given only negative results. It seems probable from the experiments described in the last section that the larvæ do not, upon being ingested, immediately penetrate the lining of the upper part of the alimentary tract. It is possible, however, that they do so lower down, and then migrate to their final position, either through the tissues and cavities of the body or by way of the blood-vessels, as do many other nematodes.

In order to test the possibility of migration through the blood-stream, one of us (A.L.S.) performed the following experiment:—

On May 6, 114 living and active larvæ of the cattle *Gongylonema* were placed in 6 c.c. of normal saline solution. After thorough shaking up, 3 c.c. of this suspension of larvæ were injected into the right jugular vein of each of two sheep. These sheep were killed on July 30 (85 days after the injection), but no evidence of infection with *Gongylonema* could be found on post-mortem examina-

tion. The negative result of this experiment suggests that the normal route of migration is not by way of the blood-stream, but too great importance should not be attached to it.

SUMMARY.

(1) Two pigs were successfully infected with the common *Gongylonema* of ruminants by feeding them with cockroaches (*Blattella germanica*) which had, in their turn, been experimentally infected by feeding with the eggs.

The facts that the adult worms obtained from the pigs occurred mainly in the epithelium of the mouth and tongue, and that they were of small size, comparable with that described for the supposed distinct species recorded as naturally occurring in pigs, but considerably below the average for the ruminant form, suggest that:—

(*a*) The ruminant form, *G. scutatum*, is (as has been suggested on morphological grounds) indentical with the pig form, *G. pulchrum*.

(*b*) The pig and, by analogy, man are probably "accidental" hosts for the species.

(2) The infective larvæ of the *Gongylonema* of ruminants have been shown experimentally to emerge spontaneously from their insect intermediate hosts when these are killed and placed in water. The larvæ are capable of living in water for some days, and water must, therefore, be looked upon as a possible source of infection for the final hosts.

(3) Experimental evidence suggests that the larvæ, when in water, do not possess the instinct to penetrate the skin or mucous membranes of animals with which they come into contact.

(4) No definite light has yet been thrown on the question of the history of the infective larvæ after entry into the final host, or their route of migration within the host's body before reaching their definitive position. The result of an experiment in which larvæ were intravenously injected into sheep seems to suggest that they do not normally migrate by way of the blood-stream.

YELLOW FEVER CONTROL IN WEST AFRICA.

By Prof. W. H. HOFFMANN, M.D.

Habana, Cuba.

AT the present day, when the greater part of the coast of West Africa, between Senegal and the Congo, is an endemic centre of yellow fever, it may be allowed to consider the means which we use to-day and which should be applied to prevent the disease from spreading and becoming once more a danger for the world, as it has been for centuries.

It may be, and it is probable, that West Africa was the oldest endemic centre in the world, but it was too far away to attract attention. To-day the communications have become easier; to-day the disease is quite near to the great highways of the world's traffic and to the great capitals of the world's commerce; and yellow fever has always been found following the world's traffic and commerce.

On the other hand our knowledge of the disease and its prevention is much better now than it used to be in olden times; quite sufficient indeed to allow of a perfect control, at least in civilized countries where it is possible to make the necessary hygienic measures practically effective.

This seems doubtful in Africa and eventually the disease might spread in the interior, even though its transport by sea should be preventable by the ordinary quarantine measures.

The fundamental methods in the control of yellow fever are the classical anti-mosquito measures which were worked out in Cuba in 1901, on the discovery of Finlay, made and published in 1881, that the only way of transmission of yellow fever is the transmission by the mosquito *Aëdes ægypti*, formerly known as *Stegomyia fasciata* or *calopus*. If in a certain place we can reduce the number of these mosquitoes under the critical level, if perhaps only in 1-2 per cent. or even 5 per cent. of the inspected houses larvæ are present, then yellow fever does not find the conditions to spread in an epidemic form. This can be done regularly and without great difficulties, as experiences in America have shown, with the result of immediate eradication of the disease. Not to profit by these experiences would be a neglect of elementary hygienic rules.

Aëdes ægypti is present everywhere in tropical Africa, on the Mediterranean coasts, in Southern Europe and Asia Minor; it is abundant in India and in the Far Eastern countries. The possibilities for the propagation of yellow fever, if once imported, are enormous in the tropics and subtropics of the Eastern Hemisphere.

Now we know that yellow fever epidemics generally originated from the big centres of traffic with their numerous and non-immune population, whence they would spread over the country.

This observation shows how the great problem to attack yellow fever in Africa may be resolved successfully, difficult or even impossible as it might appear at first sight to one acquainted with sanitary conditions and hygienic work in Africa.

It must be the first aim of the health authorities to reduce the number of mosquitoes in the principal harbours of the whole coast in such a way that yellow fever cannot spread further in places which are the primary and most dangerous centres. This should be possible with some energy, as it corresponds to the great danger which is imminent for the whole world.

Of course, it will be necessary that the clinical and pathological experts look most carefully for all suspicious cases, so that they cannot escape observation. Though generally it will be too late for isolation, or even for the specific treatment, because the first three to four days of the disease will already have passed, still it will be possible at a very early moment to deal with the house of the patient in order to kill the infected mosquitoes. It will be possible also to apply our second and very helpful though supplementary measure in combating yellow fever, by injecting all the persons from the environment of the patient with the yellow fever vaccine prepared from killed cultures of *Leptospira icteroides*, which will immunize those who possibly were exposed to the bite of the infected mosquitoes in the neighbourhood of the first case. Thus the disease must find a wall of non-susceptible persons which it cannot pass.

Vaccination should be made obligatory for all non-immunes, especially Europeans, who arrive in the country; or better still for all foreigners without exception.

The diagnosis of the disease in the benign form, as it presents itself in endemic areas, is not easy, especially in coloured people and in children. More care should be applied to good clinical observations of suspicious or doubtful cases, especially when occurring in foreigners, and of exact anatomical studies of all the fatal cases in which another cause of death is not absolutely obvious.

It is difficult to know how far the endemicity may reach now to the interior of Africa. Still, this is a question of serious importance, because the greatest danger, almost impossible to check, seems to be at the present moment the transport of the disease from the endemic centres of the West African coast to other territories with a large non-immune and highly susceptible population in Central or East Africa, where the importation of yellow fever would certainly produce murderous epidemics, which it would not be possible to combat by adequate hygienic measures.

The prophylactic measures against the transport by sea are much easier.

There is not much danger that an infective case of yellow fever should come to Europe, because the incubation period is less than six days and the infectivity is limited to the first three days of the disease.

The *Aëdes ægypti*, however, becomes infective twelve days after sucking the blood of an infected person. Once infected it remains infective for weeks and months. Such mosquitoes might easily reach Europe and other countries with the steamers.

The principal measures to be adopted by the neighbouring countries which are menaced, besides the regular quarantine measures and fumigation of the ships, are the same local measures against the *Aëdes ægypti* in the principal seaports, so that in the case of importation of yellow fever patients, or even infected mosquitoes, the disease cannot spread owing to the absence of the transmitting agent.

The control of the yellow fever mosquito is quite different from the well-known measures used in the anti-malarial campaign.

Aëdes is quite a domestic mosquito. It will never leave the house of man or its immediate neighbourhood. Here the female sucks blood and here she lays her eggs in the small water containers, which are found in every house, especially in a hot climate, if there is no central water supply.

The eggs will develop in about a week into a new generation of mosquitoes.

The most effective way to attack the *Aëdes ægypti* is by eliminating the domestic breeding places so that the eggs cannot be deposited and the larvæ cannot develop.

Small water containers should disappear or must be emptied at least every five to six days. The tanks which are indispensable must be screened by mosquito wire net. Where that is impossible, in America the best results have always been obtained by small fishes, of which one or two are put into the containers and which eat the larvæ. It is recommended to use fishes of the country which, by a study of their habits, may be found apt for this purpose.

The best measure against *Aëdes* is always a good pipe-water supply.

Two or three months of a vigorous campaign against the mosquitoes will generally be sufficient to reduce their number so that no epidemic is possible.

Experience has shown that the anti-mosquito measures cannot be left to the population, because even in civilized countries they will not co-operate in this work.

So in Africa still more this work has to be done under the responsibility of the health authorities and officers, by specially trained mosquito brigades, which have to go from house to house to apply the necessary measures and come back regularly every week to control the result of their work.

If these measures are applied systematically in the big centres of traffic, it will generally be possible to control the disease so that it will not spread in epidemic form, and that the endemicity will be finished in a reasonable space of time, during which the control measures have to be continued.

No special campaign is necessary for the smaller places without traffic. Here the yellow fever has always the tendency to disappear spontaneously for want of susceptible persons, because those who have once had the disease will be immune for the rest of their life.

With the modern measures of yellow fever control, mosquito campaign, especially in the big centres of traffic, early diagnosis and isolation of all the cases, protection of non-immunes by vaccination, serum treatment of early cases, with good will and energy of the responsible authorities, I think that even under the difficult conditions in Africa it will be possible to successfully attack

the disease with the final result of its complete eradication.

Immediate unanimous action is indispensable; any delay might be of disastrous consequences for the whole world. Everything possible should be done now in order to avoid in the great world of modern commerce the reappearance of yellow fever with all its horrors of bygone centuries, especially in the least protected countries around the Indian Ocean.

An unusual Type of Pemphigus; Combining Features of Lupus Erythematosus (F. E. Senear and B. Usher, *Arch. Dermatology and Syphilology*, June, 1926).—The peculiar clinical features of the dermatosis described make it difficult to determine beyond dispute its proper place among cutaneous disorders, embracing as it does features both of pemphigus and lupus erythematosus, and yet not conforming to the ordinary picture of either one of these conditions; it is possible that the disease presents a toxic eruption which should be regarded as a transition between lupus erythematosus disseminatus and pemphigus.

The Epidemiology of Malaria in Palestine. A Contribution to the Epidemiology of Malaria (I. J. Kligler, *The American Journal of Hygiene*, May, 1926).—In this paper an analysis has been given of the factors entering into the epidemiology of malaria in Palestine and an attempt has been made to analyse these factors in order to ascertain which of them are principally concerned: (1) in the annual recurrence of epidemics, and (2) in the seasonal occurrence of these outbreaks. In the first part of the paper the author has shown that the distribution of the rain, as well as the total annual precipitation, are chiefly responsible for the yearly variation in the number and extent of breeding places and hence of anopheles; and that, because the temperature and humidity show but little variation, the rain factor is the principal one which predetermines the occurrence of an epidemic in any given year or at any given place. The carrier and a susceptible population are present in abundance at all times, but the intensity of an epidemic in a given locality naturally depends on the size of the new susceptible population. With regard to the seasonal occurrence, it is shown that it depends on the anopheles vectors, which in Palestine have limited seasonal prevalence. The spring epidemic is due to *Anopheles clutus*, which has its maximal development during May and June. The autumn epidemic is presumably due to *A. sergenti*, which has its maximal development in September, but *A. clutus*, which has another optimal period in October, undoubtedly also plays a rôle in it. A hypothesis is advanced to explain the predominance of *Plasmodium vivax* in the spring and the early summer and of *P. falciparum* in the late summer and early autumn. It is argued that just as the different species of anopheles have different temperature optima, so the different species of parasites may also have different temperature optima.

Notices.

BUSINESS AND GENERAL.

1.—The address of The Journal of Tropical Medicine and Hygiene is Messrs. Bale, Sons and Danielsson, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to The Journal of Tropical Medicine and Hygiene exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All literary communications should be addressed to the Editors.

4.—All business communications and payments, either of subscriptions or advertisements, should be sent to the Publishers of The Journal of Tropical Medicine and Hygiene. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is Thirty Shillings per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—Special Notice.—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to 25 reprints, free of charge.

14.—Authors desiring additional reprints of their communications to The Journal of Tropical Medicine and Hygiene should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

Reprints.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

		£	s.	d.
50	copies of four pages	0	16	6
100	„ „	1	3	3
200	„ „	1	6	6
50	copies beyond four up to eight pages	1	13	0
100	„ „ „	2	6	0
200	„ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

OCTOBER 15, 1926.

TULARÆMIA.

The source and character of the infective agent in many cases of septicæmia often present very puzzling characters and are difficult of recognition. In fact the term cryptogenic septicæmia has been

employed to connote just these conditions, and as an example may be quoted sporadic cases of septicæmic plague. Within recent years cases of this nature have been observed to occur in various countries in persons whose avocations have brought them into contact with rodents, and particularly with rabbits, such as rabbit fanciers, farmers, gamekeepers, poultrymen and meat cutters. The cause has now been ascertained to be the *Bacterium tularense*, and the resulting infection is known as tularæmia. This organism was first described by McCoy in 1910, when investigating plague among ground squirrels, which are the wild rodents of California. Many of these animals suffered from a plague-like disease in which the pathological lesions found presented a close resemblance to those of plague, but in which *Bacillus pestis* could not be found. By subcutaneous, cutaneous, nasal and intraperitoneal injection the disease could readily be transmitted to guinea-pigs, rabbits, mice, monkeys and gophers, whilst rats were moderately susceptible and cats, dogs and pigeons appeared to be immune. The lesions produced in subacute and chronic infections strongly resembled those of tuberculosis. McCoy suggested that in natural infections the flea might serve as a carrier.

The organism is a minute rod, encapsuled as observed in infected tissue, though no distinct capsule can be seen in artificial cultures. No growth occurs on simple media, but the addition of egg-yolk, serum, blood or glucose to agar constitutes a medium on which a scanty growth of low virulence is obtained. The addition of a piece of rabbit spleen or of the spleen of the affected animal stimulates the growth and increases the activity of the organism The amino-acid cystin is a potent activator of its growth, and on serum glucose agar containing ·02 per cent. of cystin luxurious growth is obtained.

The first human case of tularæmia appears to have been recorded by Wherry and Lamb in 1913, the patient being a man who was employed as a meat cutter in Cincinnati, infection having taken place through the eye, and several cases of tularæmia conjunctivitis have subsequently been recorded.

The symptoms of tularæmia are those of a general septicæmia, with long-continued and debilitating fever, and with or without lymphadenitis in the neighbourhood of the infective focus. It often presents a fatal termination.

Even when not fatal, tularæmia is a serious disease, incapacitating the patient for several months. One very striking feature of this disease is the very large number of infections which have occurred among laboratory workers who have handled the cultures or been intimately connected with the study of the disease. The proportion attacked is probably unequalled in the history of the investigation of infectious diseases, and this fact would indicate the high infectivity of the organism and the great susceptibility of man. It is suggested that in these laboratory infections the portal of entry of the organism is in the hands, as in some of the cases there were enlarged, painful and tender lymph glands in the epitrochlear and axillary regions.

The infection has been transmitted experimentally from animal to animal by certain biting flies, by fleas, by lice, and by bed-bugs. The vector most commonly effective in the ordinary transmission of the disease from wild rodents to man appears to be some blood-sucking fly such as *Chrysops discalis* or *Stomoxys calcitrans*.

It is quite possible that human infections have hitherto sometimes escaped recognition. The diagnosis may be confirmed by blood-culture, by agglutination and by complement-fixation tests. As regards prevention of the disease it may be pointed out that there are comparatively few biting insects which feed indifferently upon small rodents and upon the human subject, otherwise tularæmia would become a widely prevalent human disease occurring in severe epidemics like plague. Susceptible animals and suspected insects should be thoroughly studied, so that effective measures of control may be evolved. Meanwhile it is unwise to handle wild rodents, dead or alive, especially in the warm seasons of the year, when they are plentifully infested with blood-sucking insects. Lastly, for their own protection, all laboratory workers engaged with this disease and its causal organism should wear gloves, and thus avoid contact of infected material with the hands.

So far as we are aware, the only cases which have occurred in this country have been restricted to laboratory infections, but that tularæmia may possibly be a disease of widespread geographical distribution and when recognized may have masqueraded under other names is suggested by a critical examination of the recent work of Ohara in Japan. His published descriptions deal with an acute febrile disease which was transmitted to man by wild rabbits in the Abukuma Mountains, to the north-east of Tokyo. He observed the condition in a mother and two sons who were all simultaneously affected after skinning, dressing and eating a wild rabbit. From inquiries it was learnt that a disease of this nature had been prevalent among the villagers of the Abukuma Mountains for the past twenty years. Ohara gained the impression that the infection is by no means uncommon in that district.

From a critical study of the epidemiological, clinical, bacterial, pathological and experimental observations of Ohara, together with the results obtained from the investigation of material supplied by Omara, Francis and Moore, of the United States Public Health Service, have been led to the conclusion that Ohara's disease occurring in Japan and tularæmia occurring in the United States are in every way identical.

They found that the clinical and epidemiological characteristics of Ohara's disease agree even in minor details with those of tularæmia. Further serums collected from his cases and forwarded by Ohara agglutinated *Bacterium tularense*, whilst glandular tissue from one of Ohara's human cases caused tularæmia in laboratory animals in the United States from which *Bacterium tularense* was recovered and reciprocal agglutination absorption

tests failed to distinguish any difference between the Japanese and American cultures.

In view of the close association between tularæmia and the wild rabbit and of the wide geographical distribution of this animal it may be expected that in the course of time cases will be recorded from other countries and Australia would certainly be expected to rank among them, for, as is well-known, the wild rabbit is there so prevalent as to constitute a national pest.

Annotations.

Studies on the Serology of Leprosy, II. Nitric Acid Precipitation (Bruck, modified) (H. W. Wade, *The Philippine Journal of Science*, May, 1926).—A study of the serum of leprosy has been undertaken by means of certain non-specific tests and by other means, in the hope of throwing more light on the changes occurring in this disease. Results with the nitric acid reaction of Bruck, somewhat modified as to technique, are reported. Of 100 lepers' sera tested, 93 were read moderately to very strongly positive, and none was negative. Antileprosy treatment apparently reduces the degree of reaction, it being very strong in a much smaller proportion (7 per cent.) of the cases that have been under treatment than in new untreated cases (44 per cent.). The results in ten cases clinically and bacteriologically negative were essentially the same as in the treated cases, the explanation for which fact is not apparent. The reactions in 21 sera giving some degree of the Wassermann reaction was essentially the same as in the untreated group. Of a group of 16 non-lepers, only three gave negative reactions, these among the professional staff, while two (labourers) were strongly positive. The frequency of weak reactions in apparently healthy individuals leads to speculation as to whether these weaker reactions are due to any abnormality. That this reaction is of no value in the diagnosis of a particular disease is obvious; that it does not depend upon the presence of syphilis (or yaws) alone, and does not have the significance of the Wassermann reaction, is again shown.

The Non-surgical Constipations, Functional and Mechanical (Max Erdheim, *Medical Journal and Record*, May 5, 1926).—The nonsurgical constipations may be divided into two groups, namely, those that are of mechanical origin and those that are of functional origin. But even in those cases in which roentgenological study shows a definite mechanical defect, the functional factor, i.e., a disturbance of the balance of the nervous control, is often the essential cause of the constipation. A knowledge of the physiological action of the nerves that control the intestinal movements is essential to an understanding of the functional constipations. The most rational classification of these constipations is that of Gustav Schwarz. It is based upon the present-day conception of the nervous control of the movements of the colon. According to this classification the functional constipations are divided as follows: (1) the ascending type which is commonly associated with pericæcal adhesions, typhlitis, chronic appendicitis, and cæcum mobile; (2) hypokinetic constipation, due to an underactivity of the motor vagal fibres that pass directly from the intestinal serosa to the muscular layer, resulting in spasms; and dyschesia or rectal constipation, due to a habitual suppression of the physiological urge. The principal causes of the functional constipations are an insufficiency of roughage in the diet, diminution of the endocrine secretions that normally augment peristalsis, constitutional depression of the excitability of the plexus of Auerbach, overactivity of the vagal innervation and habitual neglect of the physiological call. Whenever a patient gives constipation as his principal complaint a detailed study must be made to determine the specific causative factors operative in the individual case. The most important part of this study is the roentgenological examination. A routine treatment for the functional constipations is illogical. Rational therapy is dependent upon the specific ætiological factors in the given case.

Effect of Parathyroid Hormone on Certain Signs and Symptoms in Tuberculosis (B. Gordon, J. L. Roark and A. K. Lewis, *Journal of the American Medical Association*, May 29, 1926).—To a series of sixty tuberculous patients parathyroid hormone injections were given to determine the effect on certain signs and symptoms common to this disease. There was improvement in the strength, increased warmth and lessened muscular and pleuritic pain. In some instances, there was also a favourable effect on laryngeal tuberculosis. The effect on cough was variable; the dry, hacking cough was often aggravated, the productive coughs were often less troublesome during treatment, and there was decreased expectoration. There was a favourable effect on dyspnœa. The most striking objective feature was in the control of pulmonary hæmorrhage. This was relieved quite constantly. There was also a decrease in the œdema of the arytenoids and other structures involved in laryngeal tuberculosis, with some evidence of healing. In pleurisy and pulmonary congestion there was evidence of decreased râles following the administration of the parathyroid hormone. In the Roentgen-ray examination, there was a suggestive clearing of the lung fields, but no evidence of calcification. In general there was a favourable effect on the condition of the patients as shown by increase of appetite, gain in weight, and lowered temperature and pulse-rate. The untoward features

were arthritic pains, dryness of the throat, increased coughing, palpitation, weakness and periods of elevated temperature and pulse with loss of weight and appetite, and were usually due to over-dosage. These phenomena were generally relieved following the withdrawal of the medication, and seldom re-appeared during moderate dosage. There appears to be no evidence that a favourable effect on pulmonary tuberculosis is obtained from maintaining a high calcium content in the circulating blood.

Studies on the Serology of Leprosy, I. *The Wassermann Reaction in Leprosy* (E. V. Pineda, *The Philippine Journal of Science*, May, 1926).—The Wassermann reaction was made, using Kolmer's method, on the sera of 500 lepers, and, for comparison, about 150 of these were also tested by an ordinary method, using both plain and cholesterinized antigens. In the latter method it was found necessary to adjust the antigen dose closely, as an increase from the dose used, 2½ antigenic units to 4, resulted in an increased number of weakly positive or doubtful reactions. The 500 cases considered include 66 untreated new admissions and cases that were under treatment at the time or that had been treated. Among the latter 59 were negative and 82 were cases of lepra reaction. Of the total group 85, or 17 per cent., gave reactions that were positive in some degree, the doubtful plus-minus reactions being included. Of these, 58 were in the group of 67 cases that were under suspicion of yaws (42 cases) or syphilis (25 cases). In the remaining 27 positive cases neither history nor signs of yaws or syphilis could be elicited. Data on the clinically framboesial and syphilitic groups are given. The particularly interesting group without clinical evidence of treponematous infection is subdivided into those without and those with lepra reaction, 11 and 16 cases respectively. Of the former, 8 gave strongly positive Wassermann reactions and of the latter but one. Further, the 3 weak reactions of the former group were in cases of slight leprous involvement, and the reactions were negative on retest. The one strong reaction in the latter group was in a Moro, particularly liable to yaws.

Nature and Availability of the Plant-Food Constituents of Philippine Guano (M. Tirona, *The Philippine Journal of Science*, May, 1926).—Guano is being used on a large scale as a fertilizer by sugar planters in the Philippines, and extensive working of guano deposits in the country is in operation. Thousands of tons of guano, mainly the excreta of bats, are being mined every year, the greater part of which is sold to local manufacturers of fertilizer who use this material mainly as a source of phosphoric acid for their brands of fertilizer; the remainder is disposed of to farmers, who apply it directly to the soil. The ever-increasing demand for local guano renders it important therefore that its nature and the availability of its plant-food constituents be known; it was with this end in view that this investigation was undertaken.

Philippine guanos are, in general, phosphatic, the phosphorus existing mainly as phosphates of iron and aluminium. In freshly deposited guanos, however, the phosphorus exists mostly in immediately available form. The water solubility of nitrogen in Philippine guanos ranges from 16 to 60 per cent. of the total, of which from 3 to 15 per cent. is derived from ammonia, ammonium salts, simple amids, soluble proteids, &c., and the remainder from nitrates. An important characteristic of Philippine guanos is therefore, the relatively large proportion of nitrogen as nitrates. Potash is invariably present in Philippine guanos in quantities generally not exceeding 1·5 per cent. From 3 to 68 per cent. of this is immediately available to plants.

Ætiology of Oroya Fever. Cultivation of Bartonella Bacilliformis (H. Noguchi and T. S. Battistini, *Journal of Experimental Medicine*, June 1, 1926).—A pure culture of micro-organism resembling in morphology and pathogenic action *Bartonella bacilliformis* has been obtained from blood taken during life from a case of Oroya fever which ended fatally. The blood taken at Lima and transported to New York at refrigerator temperature yielded positive cultures twenty-eight days after its withdrawal from the patient. The strain of *B. bacilliformis* thus isolated grows well on the semi-solid leptospira medium, and also on slant agar containing animal blood. The initial growth is not readily recognizable to the naked eye, but the presence of the organisms can be determined by means of the dark field microscope and by Giemsa and Gram staining methods. No growth has been obtained on the more ordinary culture media. The organism is an obligate aerobe, is Gram-negative, and under certain cultural conditions motile. All the forms which have been described as occurring in human red corpuscles may be found in the cultures, and in addition many granular and coarsely irregular forms have been met with. The inoculation of cultures *B. bacilliformis* into *Macacus rhesus* produces infection and gives rise to effects which differ with the mode of inoculation. The intravenous injection of the culture into young macaques induces a prolonged irregularly remittent fever. The organism can be cultivated from the blood over a long period, and it has been detected within the red corpuscles of the monkeys, reproducing the precise appearances observed in human cases of Oroya fever. The intradermal injection of the culture into the eyebrow of the young macaques gives rise to nodular formations rich in new blood-vessels and showing the bacilliform organism within the endothelial cells. From the experimentally induced nodules cultures of the organism are readily recovered.

Abstract.

DESTROYING ENGORGED ANOPHELES AS A MALARIA CONTROL MEASURE.[1]

By J. A. LePrince.

The value and importance of applying emergency malaria-control measures has been stressed by Fricks, Gorgas, Howard, LePrince, Orenstein, Ross and others, and again recently in the Report of the International Congress on Malaria at Rome, Italy. The field workers of the United States Public Health Service have been studying the application of malaria control measures since 1914, and in malarious localities they find the greatest prevalence among the farm-tenant classes, many of whom are relatively poor, and malaria is not infrequently a contributing cause to their poverty. If a control measure can be devised and applied that will not necessitate any investment of capital until such time as these tenants are better able physically to carry on their daily tasks, it will be in every way advantageous to them.

Although much publicity has been given to matters pertaining to malaria control, it is not uncommon for communities and even health workers to start malaria control campaigns before studying the nature of the local problem. Not infrequently those who are assigned the task of supervising the field measures have had but little previous experience, or may be unaware of special measures which were developed and applied years ago, which, if modified, might be very well suited to the conditions surrounding the new undertaking. As a result methods that are less satisfactory, more expensive, unsuited to the problem, or doomed to failure may be adopted with unfortunate results. Such procedure has a tendency to give the neighbouring public a fixed impression that all mosquito control measures are expensive and of doubtful value.

Throughout the malarious districts of this and other countries are suburban sections of rapidly growing towns, farming settlements, industrial plant villages, construction camps and other groups of homes that have been located in sections particularly favourable to propagation of malaria-bearing mosquitoes although non-anopheles producing areas may exist near by. Such errors of selection of location are even yet common, and create conditions that may require emergency mosquito control measures. It is particularly important that this subject should be better understood and more widely known by those directing the development of industries or natural resources, and even more so by those connected with the establishing of military or naval camps. Naval, military, engineering and technical schools can advantageously give this subject the attention it deserves and thereby reduce serious losses that may otherwise occur.

Temporary emergency measures are not as satisfactory as permanent mosquito eradicative measures; yet at times they are an excellent substitute and can often be made of decided importance in opening up new territory, in engineering construction operations, in colonization, in developing agricultural lands in malarial territory, and in naval and military campaigns. A large economic loss is continually going on for the lack of their application. In districts of relatively high anopheles prevalence, where construction operations or other activities are to be undertaken, labourers or settlers are attracted, and among these people may be sufficient malaria carriers to create conditions favourable to a serious outbreak of malaria. Conditions may or may not be favourable for the control of malaria carriers by means of quinine treatment. In nearly all cases, however, the people will be friendly toward any reasonable action that will reduce or destroy the mosquitoes that annoy them. Where a large portion of the new arrivals come from non-malarious territory and mix freely with the malaria carriers in the presence of anopheles, an emergency situation may arise. In very few similar situations are precautionary operations against anopheles production undertaken sufficiently far in advance. They certainly were not at the Panama Canal, nor more recently when we located our military cantonments in the most malarial sections of the south.

It is not unusual for the best plans for permanent anopheles eradicative measures sometimes to fail temporarily and thus create conditions requiring prompt application of auxiliary malaria control measures. Among such causes might be mentioned the following: (1) A reduction of working appropriations; (2) shortage of larvicides; (3) a shortage of screen; (4) a shortage of quinine; (5) a supervising official not in sympathy with anti-mosquito work; (6) a change of directing officials; (7) man-made changes of topography; (8) influx of people from highly malarious districts; (9) an unusual rainy period or season; (10) natural changes of topography; (11) sudden and unforeseen appearance of aquatic plants in quantity in bodies of water, wind-driven flotage on (tidal) fresh-water rivers, such as large rafts of eel grass, stream-borne flotage on lakes or from highlands to rivers affected by tides; (12) unexpected reduction of natural mosquito enemies due to unusual seasonal or other causes.

During the construction of the Panama Canal frequent emergency conditions arose or were unnecessarily created which are described in "Mosquito Control in Panama." We can expect similar and also new unexpected conditions and problems to arise with other species of anopheles, and they must be solved locally by sanitarians. Those who are detailed to direct anopheles control campaigns should consult all sources of information and combine the findings of others with a bountiful supply of common sense in directing malaria control operations.

The remedy for the emergency situation can often be best determined by a close study of the habits of the local anopheles, which may vary considerably with different species and in different localities. At Panama the most important of the

[1] **Abstracted from the *United States Public Health Reports*, June 18, 1926.**

malaria-carrying anopheles were the *albamanus* and *tarsimaculata*. The latter, during the dry season, rested in ground cracks in the day time. By placing small bundles of hay under the house they were induced to ignore the ground cracks and to collect in the small piles of hay. Members of the species at Gatun did not rest on the wooden beams under occupied houses as our *Anopheles quadrimaculatus* does. They would collect under certain houses in the day time but never under certain other houses near the selected ones.

A close study of the problem has shown that a knowledge of the habits common to many anopheles may be used to advantage by sanitarians in practical malaria control. The following are some of the important points to be kept in mind:—

(1) After many species of anopheles become engorged they rest on the wall or suitable shaded resting place relatively close to where they obtained their blood-meal, and it is not usual for them to fly for a considerable time after becoming engorged.

(2) Those which have digested their blood-meal and are ready for flight depart from their day time resting place (house or enclosure) either (*a*) soon after dusk, or (*b*) soon after daylight.

(3) In the screened building the anopheles, ready to depart, collect on the window screens and doors during these periods, and, with a little care and practice, practically all of them may be destroyed. While on the screens they appear to be more interested in escaping from the building than from the person who is destroying them.

(4) The recently engorged anopheles at rest on the walls of the building are relatively easy to destroy. If they are rather closely spaced, a chloroform bottle or a Griffitt catching tube may be used to advantage for collecting them; but ordinarily the common fly swatter will be found of more practical use.

(5) Light-coloured walls make the task an easier one. In relatively dark rooms a flash-lamp or other suitable artificial light (but not too bright) is an advantage in obtaining perfect results.

At the farm-tenant homes where the family has insufficient funds to protect themselves from malaria by making the home mosquito-proof, it is known that a considerable reduction in malaria transmission can be accomplished by systematically destroying the anopheles that are to be found each morning resting on the walls of the bedrooms. This is effective where no attempt has been made to screen the building.

Most of our malaria in the United States is conveyed by *Anopheles quadrimaculatus*. This mosquito very rarely bites in the full sunlight and does not like bright lights. It is a night feeder, but will at times attack man in houses in the day time. When it bites us at our homes, in most instances it rests on the walls of the room where it took its blood-meal and remains there quietly for a day. Occasionally some of them go into adjacent rooms. After taking the blood-meal this particular mosquito appears to be more sluggish and it is not as easily alarmed as are some other kinds of mosquitoes. It is relatively easy to destroy, and children, after a few trials, are soon able to find all mosquitoes resting on the walls. On rough wooden walls the resting anopheles look like wooden splinters that stand out from the flat surface. It is possible for the children in the farm-tenant homes to learn how to find and destroy every anopheles in the room, and they enjoy doing it.

If these mosquitoes on the walls are destroyed at a definite hour each morning then malaria transmission will practically be prevented in that home. There are many localities in which eradication of anopheles by drainage may not be undertaken in the near future and where the farm tenants cannot screen their homes. In such places this control method can be used to advantage.

Many persons, when bothered by pestiferous mosquitoes or when moving into a malarial district are likely to confine their precautions to the use of mosquito lotions and a mosquito bed-net. In tents and in dark bedrooms at times we find anopheles resting on these mosquito bars by preference, and careful observations indicate that a considerable number of persons can be bitten through the cotton mosquito bed-net while asleep and can be entirely unaware of the fact the following morning. This may be because the bite of some anopheles is less painful than that of other more pestiferous mosquitoes. Before a person is ready to accept or apply any health control measure suggested he is likely to want to know what results may be expected from the efforts expended.

During the building of the Panama Canal, Gorgas used the anopheles control method above-described on a large scale in the native thatch huts, at labourers' barracks, in railroad bunk cars, and in both screened and unscreened residences. The results were highly successful, the accounts of which were published.

In 1908 a temporary labourers' camp, consisting of tents, was established near the site of the present Miraflores Locks and used for four and a half months during the rainy season, when malaria transmission is most frequent. This camp was completely surrounded by extensive untreated anopheles breeding places. A labourer with a fly swatter and catching tube was employed to destroy all the anopheles he could find in the tents. Each tent was examined soon after the labourers left each morning. The malaria incidence among the labourers in these tents was thus kept down to 4 per cent. per month, or the normal rate at that time for the Canal Zone labourers sleeping in screened buildings at camps where mosquito control work was being done. No attempt was made to screen the tents in this camp, and the labourers were free to go to any other camps after dark. Some of them did go. Their night visits to other localities may have had a relation to the malaria that appeared at this camp. This malaria sick rate was less than 7 per cent. of the rate of our troops living in well-screened barracks located three miles away. At both places the malaria-conveying species of anopheles were very numerous.

Another instance of the value of daily destruction of anopheles in sleeping quarters in the same

year was at Diablo Hill, about three miles from the City of Panama. United States Marines were stationed in well-screened barracks on the hilltop and had a weekly malaria sick rate of 14 per cent. The camp of the railroad labourers was between the same hill and a prolific anopheles-producing swamp. A negro was engaged less than an hour each morning to destroy all the anopheles he could find in the bunk cars of this railroad camp. The anopheles that gained entrance to the soldiers' barracks were not destroyed. The malaria sick rate of the United States Marines was 42 times that of these railroad labourers, and the camp of the latter was at the edge of the swamp, and the screen doors of the bunk cars were kept propped open by the labourers after dusk.

Again, during the period of relocation of the Panama railroad, the jungle was being flooded by the slowly rising waters of Gatun Lake, making an excellent breeding area for anopheles. Very little was done in the matter of controlling the extensive breeding places of anopheles with which many of these temporary "relocation camps" were surrounded. The labourers' camps were located close to the water, and native villages were built close to them and contained many malaria carriers. These camps were strung out along a line of about twenty miles of right of way. At these settlements and camps a daily mosquito catch was made. The malaria incidence, even under these conditions, by means of daily destruction of engorged anopheles, was kept as low as the incidence of the Canal Zone as a whole, where mosquito production was under excellent control at many camps. It was even lower than at some of the camps in the hill country where hand catching was not used and where labourers lived in well-screened houses. Moreover, during a period of several months the anopheles in native houses and in camp cars in the lake region (Panama Railroad relocation) were all taken alive and sent to the laboratory for dissection, and no infected specimen was found, indicating that, for all practical purposes, this daily catch emergency control method was decidedly effective. All anopheles that were collected in the careful daily catches were caught before they had time to become infected.

Equally good results were obtained during the historic flight of anopheles at Gatun in 1912, when *Anopheles torsimaculata* from a hydraulic fill containing blackish water became sufficiently numerous to compel the clerical force to cover cane-seated chairs with blotters and to use paper leggings held in place by elastic bands, as protective measures. This control method was also used with considerable success at Carazol and at Miraflores, where more than 1,000 anopheles were caught in a single night in a small, properly designed, double-flare mosquito trap about 2ft. long and 18 in. high. At one time the weekly catch of anopheles that gained access to dwellings in the Canal Zone varied from 7,000 to 22,000.

Recently, at a farm home on the coast of Georgia, where the little children of the family were badly infected with malaria, listless and apparently not used to enjoying life, great excitement and interest was aroused when a play-game was made up to capture the engorged anopheles resting on the walls of the bedroom and porch. There was lively competition to see who could get the most mosquitoes, and in a short time the children were laughing and thoroughly enjoying the work. Unquestionably in future years better and more economical methods of anopheles eradication than are now employed will be devised, but in the meantime we can advantageously apply such a method as the one outlined. It is thought that its practical use and value to our farming population of malarial districts is sufficiently important to cause sanitarians to make it better known and more widely employed.

Current Literature.

INDIAN MEDICAL JOURNAL.

July, 1926.

Prickly Heat (H. W. Acton).—This affection is known under several names, of which prickly heat is the commonest. It is a staphylococcal infection of the mouths of the sodden sweat ducts. These staphylococci may be derived from the skin, but more frequently from an existing seborrhœa of the scalp. The staphylococci of the scalp are strewn all over the body, either by falling from the head or through the agency of clothes or towels. Excessive perspiration causes the epithelium of the mouths of the sweat ducts to desquamate; this is brought about by excessive exercise or increase in the temperature and humidity. Rough and warm clothing tend to the extension of the disease, by causing either excessive perspiration or exfoliation of the horny layer. The staphylococcal infection is best controlled by keeping the skin dry with an antiseptic dusting powder. The treatment of the primary lesions of the scalp is to prevent the staphylococci from being scattered all over the body.

The Diagnosis of Typhoid-like Fevers, with Special Reference to Typhoid and Kala-azar (G. Shanks and G. P. Khan).—The methods for arriving at a diagnosis in patients with typhoid-like fevers are discussed, and illustrations of the difficultes are cited. Particular emphasis is laid on methods involving culture of the blood and examination of its serum reactions with special reference to cases of typhoid and kala-azar. Dreyer's standard method of carrying out the agglutination reaction has been found of great value. It eliminates unreliable results, and, while requiring care in the preparation of bacterial emulsions and the use of special apparatus, in an institution where many agglutinations have to be carried out it is more expeditious than other methods. The routine complete examination of cases of typhoid-like fever has brought to light the occurrences of some interesting associations between typhoid and kala-azar. In two of the five cases in which an attack of kala-azar supervened after typhoid it was noted that the agglutinins for *Bacillus typhosus* had disappeared within a short

interval. While in certain cases a primary *Leishmania donovani* infection may have an onset clinically resembling that of typhoid fever, followed by an interval and then followed by a further febrile illness, in others there may be a primary true typhoid infection succeeded (after a lapse) by kala-azar. In cases where the initial febrile attack is diagnosed as typhoid fever by agglutination tests a curve should be sought for, as a low titre might be the residue of some previous infection. A case diagnosed by blood-culture as typhoid fever was followed by typical kala-azar which yielded to treatment with antimony. The agglutinins for *B. typhosus* disappeared when the kala-azar supervened. Another case was diagnosed as kala-azar by the aldehyde test, and while undergoing treatment the patient developed typhoid fever, as shown by a positive blood-culture.

Tuberculosis in Bengal (E. Muir).—Tuberculosis or the " white plague " is perhaps the most fatal disease of large towns. Reports for 1921-1924 show that the number of cases are rapidly increasing, especially in Calcutta and Bengal. The death-rate of females between the ages of 15 and 20 is appalling, and if the present rate is kept up it will mean that on an average one out of every ten in Calcutta will die of this terrible plague. The chief reasons for the prevalency of this disease in India are bad housing, careless spitting, poverty, under-feeding and early marriage, and the *purdah* system. Bengal has no special sanatorium for tuberculosis at present, although a few hospitals have special tuberculosis wards.

Seven-day Dengue in Lucknow (H. Stott and V. Mangalik).—An epidemic of seven-day dengue fever occurred in Lucknow during September, October and November, 1925. It started at the Lady Kinnaird Hospital among the nurses, and was followed by an outbreak among the nurses and students of King George's Hospital. There were a considerable number of cases in the city. This malady, however, is not infrequent at Lucknow. Epidemics usually occur after the rains, somewhat later perhaps than the early cases of malaria. The incidence of secondary febrile rises, of rashes and of joint pains varies in individual outbreaks and in individual cases in the same outbreak, but the general clinical picture of the whole outbreak is a clear-cut one. Three-day dengue attacks in the outbreaks were not common, and certainly not so common as in similar outbreaks of dengue in Madras, Bombay, at sea, and in Mesopotamia. Perhaps this was partly due to the fact that most observed cases were nurses and students, amongst whom temperature records were available from the earliest onset of the fever. Mosquitoes of all varieties and sandflies were observed during the outbreak, but sandflies were few in number. For this reason it is perhaps more likely that the outbreak was one of mosquito-dengue than of sandfly-dengue, but it is impossible to state this with any certainty.

Notes on the Treatment of Benign Tertian malaria with Cinchona Febrifuge (O. A. R. Berkeley-Hill).—Conditions at the Ranchi European Mental Hospital are suitable for experimental investigation of the value of any suggested standard treatment for malaria. There is little indigenous malaria in Kanke and chances of reinfection by natural channels are small. Full laboratory facilities are available for confirming the diagnosis; the patients are under careful observation and control; whilst they can be observed for months together after the cessation of treatment. In such circumstances, 43 patients suffering from benign tertian malaria were treated in 1924-1925 at Ranchi with the standard one-month's treatment with cinchona febrifuge advocated by Acton and Knowles (1924). Only six of these patients relapsed, giving a cure rate of 86 per cent., and a relapse rate of 14 per cent. These results are very much better than those usually obtained in general hospital practice in India. Yet certain patients cannot tolerate cinchona febrifuge, whilst in others continuous administration of the prescription given tends to cause diarrhœa. A modified formula is accordingly given which may prove to be more suitable.

Bilivaccin-Cholera versus Commercial Cholera Vaccine (G. C. Maitra).—Bilivaccines were introduced into the Calcutta School of Tropical Medicine about a year ago. It is asserted that they confer lasting immunity against cholera, dysentery and other intestinal diseases when taken by mouth. Experiments were carried out and it was seen that the immunizing properties of Merck's cholera vaccine (prepared by Merck and Co., of Darmstadt) compared favourably with those of vaccines prepared locally from fresh cholera strains. There was, however, a considerable discrepancy found between the number of bacteria stated to be contained in Merck's vaccine and that calculated to be present in it by Brown's method. Although a comparative study of the results obtained by using the two preparations, the bilivaccine and Merck's cholera vaccine, apparently shows that the former protected more efficiently than the latter, yet no general conclusions can be made on this point for the comparatively poor results of Merck's vaccine may have been due to its low bacterial count.

A Trial of Oral Vaccination against Bacillary Dysentery in Indian Jails (G. C. Maitra and J. B. Basu).—Preliminary experiments have been made in India on rabbits with dysentery and cholera " Bilivaccines "; and as the results were encouraging, oral vaccination against dysentery was tried in certain selected jails in Bengal and Madras Presidencies. The two preparations used were (1) Bili-vaccine-Shiga, consisting mainly of compressed tablets of desiccated bacterial bodies (formula of Prof. Besredka); (2) a mixed and sterilized emulsion of dysentery bacilli. It would appear that the percentage incidence of dysentery among the vaccinated was appreciably reduced in both cases, but the reduction was more marked when bilivaccine tablets were used for immunization. These results call for a wide application of the same principle in fighting cholera which is a much more fatal disease and causes greater havoc in India than do the dysenteries of bacillary origin.

Original Communications.

INFECTIOUS JAUNDICE IN THE SUDAN.

By N. T. WHITEHEAD, M.C., M.B., Major R.A.M.C.,
Government Bacteriologist, Wellcome Tropical Research Laboratories, Khartoum,
AND
H. A. CROUCH, M.C., M.R.C.S., L.R.C.P.,
Sudan Medical Service.

THE following are notes on three separate outbreaks of jaundice occurring in the Sudan during the years 1922-25.

The outbreaks bear no relation one to the other, either in character or locality, nor do they accurately conform to any one type of the disease. Unfortunately, lack of laboratory facilities rendered accurate diagnosis impossible in two of the outbreaks. In the Port Sudan epidemic laboratory work was undertaken to investigate the causation and origin of the outbreak, results of which are stated later.

The authors, while realizing investigation is thus incomplete, consider the incidence and clinical picture to be of some interest.

PORT SUDAN EPIDEMIC.

Forty-seven cases occurred during the months of January, February and March, 1922. The chief *symptoms* in these attacks were jaundice—headache—pain in the epigastrium—some vomiting after food—slight fever for the first day or two (according to the patients' statements).

Signs.

Temperature.—The majority of those cases admitted to hospital showed no rise of temperature after admission, and in no case did the temperature rise above 100 or last more than three days.

Urine.—The urine of the greater number of cases was examined for albumin with negative results.

Jaundice.—Disappeared five to six days after date of onset.

The average stay in hospital was four days. None of the cases seemed to have suffered from weakness or debility after their discharge.

Epidemiology.

None of the cases gave any very definite indication that the disease was a contagious one, nor did they seem to have much connection with each other.

Most of the cases occurred singly and came from both the clean and sanitary houses of the town and the insanitary shanties of the surrounding villages.

The following set of cases show a superficial relationship, but on further investigation the connection is not of much account.

Amongst a set of nine policemen three men fell sick on the following days, February 8, 12 and 16.

The first two men lived, slept and ate in the same room as six of their comrades, none of whom contracted the disease, the third man, who was in charge of the others, had a room to himself and took his meals in the market place.

The cases that came to hospital were nursed in the general ward and no case of jaundice amongst the other patients was reported.

No European subject and no native woman ever contracted the disease.

Rats and flies were prevalent, more especially in the villages and in the market place of the town. There were no mosquitoes in or around Port Sudan.

There is one point in connection with the local customs that should be borne in mind, and this is that a large proportion of the native male population have their meals in the market place. No particulars were obtained at the time as to whether there was any connection between the cases and the various eating houses in the market, but it is conceivable that the outbreak might have been caused by food sold in the market which had been infected by some intestinal organism of somewhat low virulence.

The freedom of the women from the disease and the fact that the infection, though widespread, affected only individuals and not families seems to support the theory that the source of infection was the market rather than the home.

The *laboratory work* undertaken aimed at investigating the following possibilities:—

(1) *A Typhoid or Paratyphoid Infection.*—The blood of the last two cases was inoculated into broth, but both bloods proved to be sterile after forty-eight hours.

The fæces of seven cases were plated on MacConkey; no non-lactose fermenting organisms were grown. The urines of six cases were inoculated into broth, but again no organisms were grown.

(2) *Spirochætal Infective Jaundice.*—The centrifuged deposit of 20 c.c. of urine was injected intraperitoneally into guinea-pigs. This test was performed with three different cases, but none of the guinea-pigs were affected in any way.

The blood from another case was injected intraperitoneally into a guinea-pig, but this gave no result either. The urine was collected, centrifuged and thin smears made of all the eight cases under investigation. Two of these cases showed a fair number of spirochætes. Blood-counts were performed in each of the eight cases, and all showed a leucopenia and a relative lymphocytosis.

Blood-films showed no parasites in any of the cases.

Conclusions.

Clinically the cases were cases of camp jaundice and differed from spirochætal infective jaundice in the following points:—

(1) The mildness of the attacks.
(2) The absence of liver enlargement.
(3) The absence of albuminuria.
(4) The absence of pathogenicity of the urine towards guinea-pigs.
(5) The absence of hæmorrhagic symptoms.

Whether the spirochætes found in the urine were the causal organism of the disease or not, they were not pathogenic to guinea-pigs, and have, there-

fore, been considered as not being identical with the spirochæte of infective jaundice.

KASSALA RAILWAY CONSTRUCTION.

This outbreak occurred in an isolated working party of a British inspector and forty Berberines. The party lived under canvas in the desert alongside the railway, far removed from any habitation.

Ten cases of jaundice were reported during the months of February and March, 1924, and of these the British inspector was one of the earliest to come under treatment.

Symptoms.

Premonitory.—Fever, headache, lassitude, loss of appetite, nausea, constipation or diarrhœa.

Jaundice.—Present in all cases. In most cases became obvious on the third day and continued for nine to ten days.

Pain was complained of in four cases, the remainder experienced a sense of discomfort in the epigastrium.

Vomiting occurred in half the cases.

Signs.

Temperature at onset 100 to 101. Remained at 99 to 100 for seven to eight days.

Urine.—The urine in all cases was examined for albumin but proved negative.

Liver.—The liver was definitely enlarged in three of the cases.

Course

All cases were mild and recovery was complete in two to three weeks. One case, however, relapsed on return to work, and all the above signs and symptoms again became evident. In this instance the liver was not enlarged, but the patient developed ascites with cardiac dilatation and died.

Conclusion.

Here again, and even more so than in the Port Sudan epidemic, it seems certain that these cases were in some way connected. As stated above, local conditions made further investigation impracticable, but in view of the fact that some of the cases commenced with an attack of diarrhœa, it would seem probable that infection took place through the alimentary tract. Four to five men slept and fed in each tent, and cases were equally distributed. The British inspector and his servants lived alone and a little apart from the camp.

Food and water were brought up by train and were the same as for the main railhead camp, where no cases were reported. The camp was moved ten miles ahead every seven days.

Flies were very prevalent, but not more so than elsewhere on the line. There were no mosquitoes or any other pests.

Clinically the cases resemble camp jaundice, or possibly a mild paratyphoid infection.

MALAKAL.

During the months March-May, 1925, five cases of jaundice were admitted to Malakal Hospital. Of these, two came from the local village, two from Tonga, and one from Fungak. The latter places are some seventy miles up the river.

The cases were not related one to the other, nor was there any history of malaria, diarrhœa or syphilis.

Prodromata.

General lassitude, anorexia, headache; in one case general muscular pains.

Symptoms.

Fever.—Present in all cases at onset.

Headache.—Severe in two cases.

Pain.—All complained of pain in the epigastrium and right hypochondrium.

Vomiting.—Occurred in all cases.

Signs.

Temperature.—Onset on third day, 100-103. Duration, seven to ten days. Fluctuating.

Jaundice.—Appeared with the fever and lasted ten to twelve days.

Bowels.—Three cases had marked diarrhœa; none were constipated.

Liver.—Enlarged one finger's breadth in three cases.

Lungs.—Two cases developed bronchitis on the fifth day.

Heart.—Cardiac dilatation occurred in one case.

Urine.—There were traces of albumin in three of the five urines examined.

Complications.

One developed tympanitis, two bronchitis, one general myositis and one cardiac enlargement. The latter died.

Conclusion.

From the above it will be seen that these cases were of a more severe type than those of the other two epidemics, but they do not appear to be connected one with another in any way, nor is there any evidence of their having a common origin.

It may be remarked that all three epidemics occurred at the same time in the year, that is at the beginning of the hot weather, when flies are particularly prevalent.

BRONCHO-SPIROCHÆTOSIS.

By ALDO CASTELLANI, C.M.G., M.D., F.R.C.P.
Director of Tropical Medicine, Ross Institute, London.

AT the kind request of many medical men residing in different countries I propose, in this paper, to give a brief general account of broncho-spirochætosis.

DEFINITION.

Broncho-spirochætosis, *sensu lato*, is a term used to cover all bronchial and broncho-pulmonary conditions associated with the presence of a large number of spirochætes in the sputum, which are, in all probability, the causative agents.

SYNONYMS.

Pulmonary spirochætosis, broncho-spirochætosis. Castellani's bronchitis (Galli-Valerio), bronchite sanglante de Castellani (Violle).

History.

The history of broncho-spirochætosis is, briefly, the following: In 1904, in Ceylon, two natives came to consult me for recurrent hæmoptysis. I kept them under observation for many months, but never succeeded in finding the tuberculosis bacillus. The sputum, instead of the bacillus of tuberculosis, contained an enormous number of spirochætes, in fact, in the bloody portions of the expectoration these parasites were practically the only organisms present. The spirochætes almost completely disappeared during periods of quiescence, to reappear again in large numbers every time the symptoms became acute. I came, therefore, to the conclusion that there was probably a form of hæmorrhagic bronchitis of spirochætic origin. Later I came across other cases. My work was confirmed by Branch in 1907 in the West Indies, and by Jackson in 1908, and in the Philippine Islands. In 1909 Waters described numerous cases of the disease occurring in India, and Phalen and Kilbourne described a case in the Philippine Islands where, in 1911, Chamberlain recorded two more cases.

In 1913 Chalmers and O'Farrell carried out an investigation on the malady in the Sudan, and succeeded in reproducing it in a monkey. In 1914 Taylor investigated the condition in Uganda. In 1915 Fantham published a classical paper on *Spirochæta bronchialis*, studying it completely from a morphological point of view; he described its granular stage and the intracellular forms of the parasite.

In the same year Macfie reported cases from West Africa, and Galli-Valerio recorded several interesting cases of the malady in Switzerland, and Lurie and myself one in Serbia. In 1917, Violle first noted the affection in France, and a number of cases were reported by Beau, Dide and Ribereau, by Netter, Dalimier, Barbary, and others. In 1919 Farah described several cases in Egypt, and Alcock a case occurring in a British soldier, in Northern Italy. Villa and Corvetto and, more recently, many other observers have recorded cases in South America; Clark and Facio in Central America; Mendelson in Siam; Levy, Bloedorn and Houghton and many other observers in North America; Broughton-Alcock and Browne in England, and Iaconó, Trocello, Franchini and others in Italy. An interesting communication on broncho-spirochætosis in China has been published by Faust; Mouchet and Van Nitsen have found the disease in Katanga, and De Mello and De Andreds have reported cases from Portugal. Special mention must also be made of the very complete paper by Farah in the Journal of Tropical Medicine and Hygiene, April 2, 1923. The important work by Johns and Maes must also be mentioned.

Geographical Distribution.

The disease has a cosmopolitan distribution, but it is apparently more common in certain parts of the tropics and subtropics than in the temperate zone. It has been reported from practically every country in the world and during recent years numbers of cases have been placed on record in the United States, and a few in England.

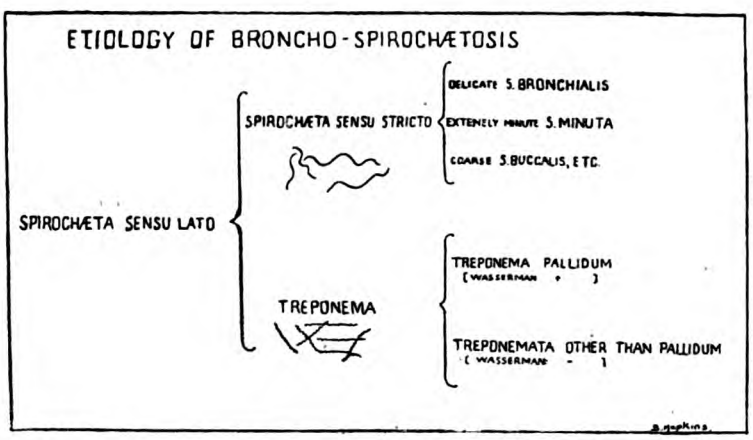

Fig. 1.

Ætiology.

The spirochætes found, as I noted in my first publications, may be of very different morphological appearances. In the present state of our knowledge, I think that the following classification might be accepted for practical purposes by the clinician:—

(*a*) The spirochætal organisms present a few spirals or coils of different sizes: *Spirochæta sensu stricto*.

(*b*) The spirochætal organisms present numerous small equal undulations close together: *Treponema*.

The first group may be divided into two subgroups:—

(1) The spirochæte is very delicate—*Spirochæta bronchialis*, *Spirochæta minuta*.

(2) The spirochæte is of coarser appearance—*Spirochæta buccalis*, *Spirochæta vincenti*, &c.

The second group may also be divided into two subgroups:—

(1) *Treponema pallidum* (Wassermann positive).

(2) Treponemata other than pallidum (Wassermann negative).

Spirochæta bronchialis.—With regard to the spirochæte which I called *bronchialis* in 1907, it has been thoroughly studied by the distinguished protozoologist, Professor Fantham.

The spirochæte is extremely polymorphic; its length varies between 3 and 30 microns, its breadth between two-tenths and six-tenths of a micron. Fantham noted two principal types: those having a length of 7 to 10 microns and those having a length between 14 and 16 microns; he believes that the former originate by a transverse division from the latter.

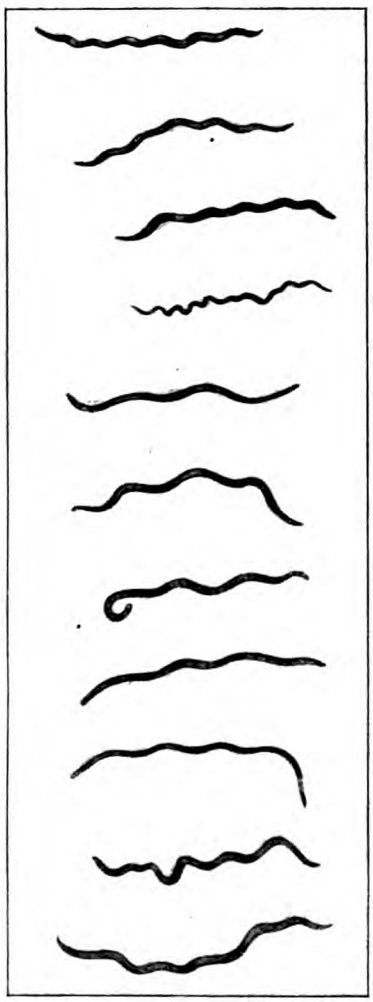

FIG. 2.
Various types of *S. bronchialis* (after Fantham).

Spirochæta bronchialis, according to Fantham, Chalmers and O'Farrell, differs from the common mouth spirochætes in the following points: (1) It is more actively motile. (2) It dies very quickly in fresh preparations of sputum. (3) It is stained with more difficulty. (4) According to Fantham, there is an intracellular stage, which is absent in the common oral parasites.

Spirochæta Minuta.—This is an extremely minute spirochæte which I found in certain cases of broncho-spirochætosis following spirochætic rhino-pharyngitis. It is very delicate, more delicate than *S. bronchialis* and most organisms present only one or two undulations. It can be put in evidence by the ultra-microscope, or by staining with various modifications of Romanowsky, the best for this particular spirochæte being apparently Jenner's modification. Silver methods of staining (especially Fontana-Tribondeau's technique) give good results. In preparations stained with Romanowsky, or other modifications of this method, the

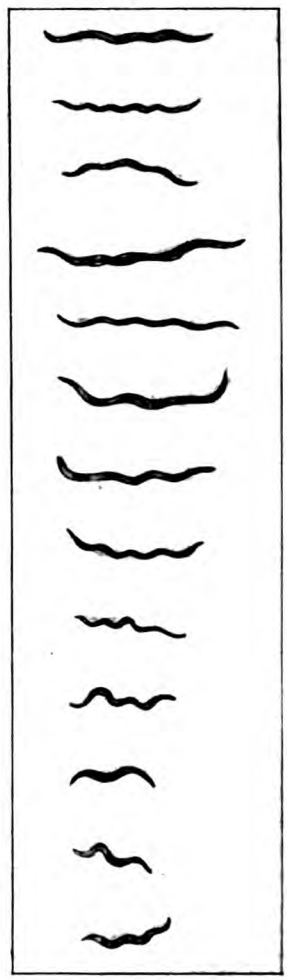

FIG. 3.
Various types of *S. bronchialis* (after Fantham).

organism often takes a pinkish-red or purplish tinge. The length of the organism varies from three to six, ten, or twelve or more microns. The beginner should be careful not to mistake for spirochætes undulating fibrin threads, particles of detached ciliated epithelium and detached cilia.

Spirochæta buccalis.—This term covers probably several species which are generally coarser than *S. bronchialis*. With regard to *S. vincenti*, a descrip-

tion of this organism was not given by Blanchard when he named this parasite, and Professor Fantham believes that this term cannot stand according to the rules of nomenclature

Treponemata.—Treponema pallidum may localize itself to the lungs and there is no doubt that cases of syphilitic broncho-pulmonary spirochætosis occur. I saw a typical case at Taranto some years ago which had first been diagnosed as pulmonary tuberculosis. In such cases Wassermann is positive. Other treponemata may also apparently cause broncho-spirochætosis, especially the purulent type.

In the cases due to treponemata other than *T. pallidum* Wassermann is negative.

Organisms found in Association with the Spirochætes.

It is seldom that the spirochæte is found alone. It is usually accompanied by various bacteria: streptococci, pneumococci and, also at times bacilli of the fusiform type and an organism which Chalmers and I used to call *macro-vibrio*, are present. The fusiform bacillus is a long fusiform straight bacillus, the macro-vibrio of Chalmers and myself and Kline is curved, comma-like, at times banana-like, of large size, very motile, possessing one or several cilia or flagella.

Predisposing Causes.

In some types of broncho-spirochætosis a chill often acts as a predisposing cause.

Method of Infection.

According to Chalmers and others, in some types of broncho-spirochætosis infection takes place from affected to healthy persons, the spray exhaled in coughing being contaminated with the spirochætes or with the resistant coccoid bodies. According to other authorities, *Spirochæta bronchialis* and the other spirochætes found in cases of broncho-spirochætosis are always present in the mouth; a chill, an operation, &c., may decrease the organic resistance of the carrier and increase the virulence of the organism in a way somewhat similar to what is the case of pneumococcus and other micro-organisms.

Experimental Reproduction.

Chalmers and O'Farrell reproduced the Sudan type of the disease in monkeys. Attempts to infect guinea-pigs always failed. The putrid type of the condition has been experimentally reproduced by several observers (Davis, Kline and Blakenhorn) in rabbits by intrabronchial injection of material from dental caries containing innumerable spirochætes and also fusiform bacilli and the macro-vibrios.

Morbid Anatomy and Histopathology.

The morbid anatomy and histopathology of broncho-spirochætosis have not yet been completely investigated, but important work on the subject has been carried out by Johns, Duval, Davis, Franchini, Kline and others. I have seen three autopsies (of the purulent type) and in all of them there was a patchy consolidation of both lungs, and in two of them there were several small foci of necrosis the size of a small pea to a cherry. The cavities varied in size up to one centimetre in diameter. The mucosa of the bronchi were swollen and injected, but no bronchiectasiæ were present. Some of the peribronchial glands were enlarged, but in none was there any caseation. The microscopical examination of stained sections showed well-marked infiltration and, when the Levaditi method was used, large numbers of spirochætes were seen. It must be noted, however, that in addition to spirochætes, other organisms were present; cocci, streptococci and organisms of the macro-vibrio type. (Fig. 4, p. 364.)

Symptomatology.

Several clinical types of the disease may be recognized, both acute and chronic.

Acute broncho-spirochætosis.—Two varieties have been described; the acute bronchial or influenzal variety and the pneumonic variety.

Chronic broncho-spirochætosis.—The following principal varieties are now generally accepted: (1) with muco-hæmorrhagic or muco-purulent hæmorrhagic sputum; (2) with purulent expectoration; (3) with putrid expectoration. Two other varieties may be mentioned; the asthmatic variety which has been studied principally by Farah, and a variety following rhino-pharyngitis spirochætica as described by me. (Fig. 5, p. 364.)

Acute broncho-spirochætosis.—This type at times resembles influenza. The onset is often abrupt, the patient feeling chilly and complaining of rheumatoid pains all over the body and developing fever which generally is not very high. The fever may last from two or three to ten or twelve days. The patient coughs a great deal and expectoration is scanty, muco-purulent, very seldom containing traces of blood. In most cases the general condition of the patient is hardly affected, in others there is great prostration. Occasionally the *pneumonic type* may be observed in which signs—generally not very typical—of lobar pneumonia are present, but this condition usually does not resolve on the seventh day by crisis and the patient is usually discharged later from the hospital as a case of unresolved pneumonia.

Chronic forms of broncho-spirochætosis—muco-purulent hæmorrhagic type. The onset is often quite insidious and slow; the patient has a chronic cough which is at times more severe in the morning. The expectoration is mucous or muco-purulent, containing now and then—in some cases constantly—blood. Sometimes genuine attacks of hæmoptysis occur, one or two teaspoonfuls or more of blood being brought up. In some cases there is no fever, in others a serotine hectic-like fever may be present. Occasionally the rise in the temperature takes place in the morning and not in the evening. In other cases the temperature chart is most irregular. The physical examination of the chest may reveal little or nothing, but in certain cases

definite signs of patchy consolidation are present. The general condition of the patient may remain fairly good for a long time, though a certain degree of anæmia is often present. In a few cases severe rapid wasting takes place. The course of this type of the disease may be very prolonged

X-RAY EXAMINATION.

In mild cases the X-ray examination shows little or nothing. In some severe cases the picture may be suggestive of tuberculosis. It may show mottling areas of patchy infiltration and diffuse peribronchial thickening.

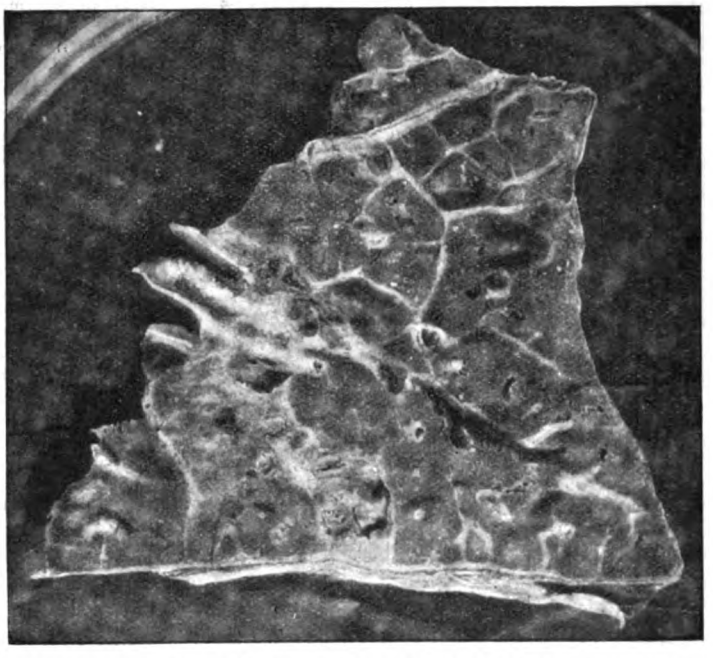

FIG. 4.—Lung in Broncho-spirochætosis of the Purulent Type. Note thickening of bronchial walls, generalized consolidation, and necrotic foci.

(*Courtesy of Dr. E. M. Johns.*)

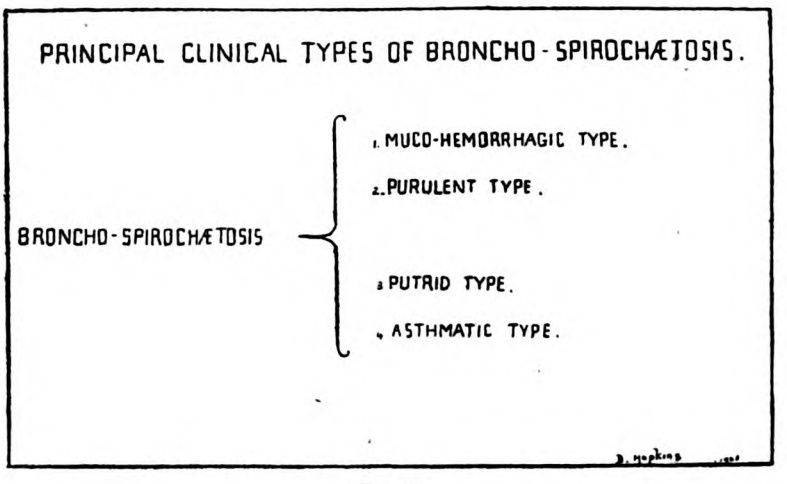

FIG. 5.

with periods of great improvement and even apparent cure. The two original cases I studied in Ceylon in 1904 were still alive when I left the Island in 1915. Cases in which blood is always absent in the sputum have been described, the sputum being mucous or muco-purulent.

Purulent Type.—In this type the patient has often a high intermittent fever and coughs up a very large amount of purulent expectoration, occasionally mixed with blood. In these cases bronchiectasiæ are often suspected, but in my experience they are not common, and no true

vomica occurs. Fever is often present and may be remittent or intermittent or very irregular. It is interesting to note that in a certain number of cases of the purulent type, the spiral organisms present are of the treponema type, and not of the spirochætic type.

Putrid Type.—The symptoms are very similar to those seen in the purulent type, but the expectoration has a very offensive odour.

Asthmatic Type.—In the asthmatic variety to which, as I have already said, Farah has paid much attention, the patient shows signs of chronic bronchitis and now and then has an attack of typical asthma.

Broncho-spirochætosis following Spirochætic Rhino-pharyngitis.—Some years ago I described rhinitis spirochætica or rhino-pharyngitis spirochætica which clinically can hardly be distinguished from an ordinary attack of coryza. In some cases, after the coryzal symptoms have disappeared or during the coryzal period, bronchitis develops with muco-purulent expectoration containing a very large number of spirochætes identical with those found in the pharynx and nose. The spirochæte in most cases of this type is extremely delicate, and for that reason I gave it the name of *Spirochæta minuta.*

Illustrative Cases of Broncho-spirochætosis.—To avoid personal equation I will report a case thoroughly investigated by Bloedorn and Houghton and published in the *Journal of the American Medical Association*, volume 76, also a case described by Iacono in the JOURNAL OF TROPICAL MEDICINE AND HYGIENE, March, 1920.

CASE 1 (Bloedorn and Houghton).—A white man aged 18, single, was admitted to the hospital complaining of headache, pains in the back and shoulders, weakness, cough and expectoration of blood-streaked mucus. Temperature 103, pulse 96, respiration 20. Teeth in good condition, no exudate on tonsils. Heart negative. Examination of the lungs disclosed only a few scattered râles at both bases, no impairment of resonance.

Clinical Course.—The patient continued to have fever with temperature varying from 100 to 102 in the morning, and 103 to 104·3 in the evening. Profuse nightsweats occurred with great regularity, and the patient during the first three weeks of his illness lost 20 lb.

There was a slight cough and rather free expectoration of a thin, muco-purulent, blood-streaked sputum. The prostration during the course of the disease was not marked, and the patient stated that he felt fairly well, but weak. The case resembled so strongly, in its clinical course, a pulmonary tuberculosis, that every effort was made to confirm such a diagnosis. The laboratory findings, Roentgen ray findings and physical examination, however, failed to demonstrate the existence of such an infection. Wassermann and Noguchi negative. During the course of the repeated sputum examinations it was noticed that, while the sputum was negative for tubercle bacilli, there were constantly present a large number of spirochætes.

The presence of these organisms was at first not regarded as significant, and it was only after repeated attempts to establish a definite diagnosis in this case that their presence was regarded seriously. Their constant presence in the sputum after the teeth had been cleansed and the throat cleared with a mild antiseptic gargle, together with the absence of a lesion of the tonsils or pharynx which account for their presence, appeared significant and strongly suggested the diagnosis of "bronchial spirochætosis."

It was decided to try the effect of an arsenical spirochæticide, and on the 20th day 0·6 grm. of neo-arsphenamin was given intravenously, and on the 21st and 22nd days the temperature again rose to 101 in the evening. On the 24th day 0·5 grm. of neo-arsphenamin was given intravenously, following which injections of 0·9 grm. of neo-arsphenamin were given at intervals of one week, although the patient had shown no rise of temperature in the meantime, and was steadily improving. Following the injections of neo-arsphenamin the improvement in the patient was striking. The prompt termination of the fever, the rapid decrease in the number of spirochætes and their ultimate complete disappearance from the sputum, the prompt cessation of the cough, and the disappearance of the blood from the expectoration, which itself became almost negligible in quantity, leave little room for doubt regarding the efficacy of these injections.

Two months following the onset of the disease the patient had regained his loss of 20 lb., had been up and about for several weeks, and was able to resume his original duties. Before discharge from the hospital he was given an injection of 10 mg. of tuberculin, following which he showed no reaction.

CASE 2 (Iacono).—Miss E. B. No previous disease of importance. Present illness began eleven days before I saw her, with general malaise, rheumatoid pains all over the body, and dry cough. The fever remained high and continued for several days, then it dropped in the morning and assumed a serotine type. Rather suspicious subcrepitant râles were found upon physical examination of the chest, in the left apex, and this fact, together with the serotine fever and sputum tinged with blood, led the family doctor to suspect tuberculosis of the lungs. When I was called in the patient was very pale and feeling very weak; upon examination of the chest, no zones of fullness were found. Moist and dry râles were present all over, but no crepitant ones. Pulse 90, pressure rather high. Heart normal. As regards the abdominal organs, the spleen was not enlarged, liver just palpable. Urine contained a trace of albumin, and there was a slight increase in the phosphates and indican. Blood: red blood-corpuscles, 4,000,000 per cm.; leucocytes, 9,000; hæmoglobin, 70 (Fleischl). As to the leucocytic formula, there was an increase in the eosinophiles and lymphocytes. No malaria parasites and no spirochætes were found. Examination of the sputum for tubercle bacilli negative. Several glucose-agar tubes were inoculated, but no fungus was grown. The microscopical examination of films from the sputum stained with Giemsa revealed presence of a large number of spirochætes of variable lengths, 5 to 20 microns, and with three to six undulations. In fresh preparations examined with the ultra-microscope numerous very motile spirochætes were seen. I made a diagnosis of broncho-spirochætosis and prescribed the mixture recommended by Castellani, the formula of which is: Tartar emetic, gr. iii; syr. tolu, ʒi; aq. chlorof., ad ʒiii; one teaspoonful in water every two hours. The patient rapidly improved and finally recovered.

MIXED INFECTIONS.

Cases of mixed infections, tuberculosis and spirochætosis, bronchomycosis and spirochætosis, are occasionally met with. It may be mentioned here that Breton and others believe that when in a tubercular patient, hæmoptysis takes place, the hæmorrhagic sputum is caused not by the bacillus of tuberculosis but by a spirochætic infection which has become engrafted on the tubercular condition. Breton is of opinion that this spirochæte differs from *S. bronchialis* and all other spirochætes.

DIAGNOSIS.

This is based on microscopic examination of the expectoration collected after rinsing the mouth and gargling with sterile water. It is essential to carry

out the examination on fresh sputum, using both the dark ground illumination and staining with one of the modifications of the Romanowsky method, or the nitrate of silver staining method such as the Fontana-Tribondeau, may be employed. The sputum, especially the hæmorrhagic part of it, teems with spirochætes, while bacteria are extremely few. The spirochætes greatly decrease in number or completely disappear when the bronchial condition improves. With regard to the diagnosis of the principal clinical types of broncho-spirochætosis, viz., hæmorrhagic, purulent, putrid, this is based on the appearance and character of the sputum; in the first variety the predominant symptom is blood in the sputum; in the second pus; in the third the putrid odour.

Broncho-spirochætosis *sensu lato* covers also a chronic broncho-pulmonary condition of syphilitic origin, with hæmorrhagic sputum, the ætiological agent being *Treponema pallidum*. In these cases Wassermann is positive while in ordinary cases of broncho-spirochætosis, including those caused by treponemata other than *T. pallidum*, this test is negative.

Differential diagnosis.—The condition has often been confused with pulmonary tuberculosis, but the examination of the sputum for the tuberculosis bacillus will be negative and animal inoculations will remain without any effect. The ophthalmo- and cuti-reactions are negative in a great majority of cases. Occasionally, however, cases of mixed infection of tuberculosis and spirochætosis occur. The affection is differentiated from bronchomycosis by the absence of fungi. Cases of double infection, e.g., broncho-spirochætosis and bronchomycosis may at times be observed, though rarely. Spirochætosis is easily distinguished from endemic hæmoptysis by the examination of the sputum which will show absence of the ova of *Paragonimus ringeri* Cobbold, and from amœbic bronchitis by the absence of amœbæ.

Prognosis.

The prognosis, except in the very severe cases of the purulent and putrid types, is favourable *quoad vitam*, but the disease runs a very chronic course, and, although periods of great improvement may take place, a true spontaneous cure is exceedingly rare.

Treatment.

Three drugs have been found useful in broncho-spirochætosis by myself and others; arsenic, tartar emetic, potassium iodide. In several cases, especially of the purulent and putrid type, salvarsan may be given intravenously in 0·3 grm. and 0·5 grm. doses once or twice a week.

The beneficial effect of salvarsan and neosalvarsan has been emphasized by Galli-Valerio, Bloedorn and Houghton and many other observers. When the patient objects to intravenous therapy, stovarsol may be given by the mouth, two or three tablets daily for a period of ten to fifteen days. Potassium iodide is useful in some cases, especially those with scanty expectoration and a tendency to asthma. Iodine-oil preparations, such as lipiodol, given by intramuscular injection are much more efficacious than potassium iodide mixtures as observed by Farah. Of lipiodol a course of twelve injections (1 c.c. each) may be given, to be repeated after an interval of two or three weeks. The injection of lipiodol and similar preparations should be given deep into the gluteal muscles. In *mild cases* the oral administration of stovarsol will be found very useful and also mixtures containing tartar emetic alone or associated with arsenic; in a few cases sulphur seems to have a beneficial action. The following formulæ may be found useful:—

1. Tartar emetic ... ... gr. ii.
   Syr. tolu. ... ... ʒ i.
   Aq. chlorof. ad. ... ... ʒ iii.
   1 teaspoonful in water every two hours.

2. Tartar emetic .. .. gr. v.
   Sodii bi-carbonate ... ... gr. xxx.
   Glycerine ... ... ʒ iii.
   Aq. chlorof. ... ... ʒ i.

Prophylaxis.—As some of the spirochætes causing broncho-spirochætosis are probably always present in the mouth, mouth hygiene is of great importance and the teeth should be kept in good condition.

The Serological Classification of Hæmolytic Streptococci obtained from Cases of Scarlet Fever (J. Smith, *Journal of Hygiene*, July, 1926).—Hæmolytic streptococci have been obtained from throat cultures of 92 per cent. of cases of scarlet fever in the first two days of the disease. Strains from 210 cases were found to belong to two main serological types, Type I strains being obtained from 119 cases and Type II strains from 57 cases. Strains obtained from cases occurring in members of the same family were found to be mainly of the same serological type. Strains obtained from cases in small isolated outbreaks were found to be of the same serological type.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All **literary communications** should be addressed **to the Editors.**

4.—All **business communications** and **payments,** either of subscriptions or advertisements, should be sent **to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is **Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 ,, ,, ...	1	3	3
200 ,, ,, ...	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 ,, ,, ,,	2	6	0
200 ,, ,, ,,	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF

Tropical Medicine and Hygiene

NOVEMBER 1, 1926.

THE BONE LESIONS OF YAWS.

OUR knowledge of the manner in which the osseous system is affected in yaws is somewhat scanty and may be summed up as follows: Bone and joint lesions have been found to occur in about 20 per cent. of the cases of yaws inflammation of the periosteum of various bones being comparatively common. The multiple dactylitis so frequently observed in framboesial patients is due to a form of multiple periostitis of the digital phalanges, whilst other lesions of the bones may simulate tuberculosis, central septic abscesses, gummata, hydatid cysts, osteitis fibrosa, enchondromata, endotheliomata, sarcomata, myelomata and secondary carcinomata. X-ray examination reveals these bone lesions as irregularly oval rarefied areas usually in the long axis, parallel with that of the bone. They vary in size, ranging from a few millimetres to two or three centimetres in length. The great majority of the lesions appear to originate in the interior of the bone, although a few of them seem to produce small excavations in its outer surface.

These conditions have been carefully described and reviewed by Mr. Lawford Knaggs[1] who includes a chapter on the affections of the bones in yaws in his recently published studies of the inflammatory and toxic diseases of bone, in which he points out that yaws presents such a great resemblance to syphilis that the late Sir Jonathan Hutchinson suggested the name "framboesial syphilis" for it, a controversy having raged for many years whether yaws is merely a modified form of syphilis or a distinct and separate disease. The latter view now prevails, the causal organism, *Treponema pertenue* of Castellani, having definite characters of its own, although it closely resembles *Treponema pallidum* of Schaudinn in appearance.

Yaws, too, presents primary, secondary and tertiary stages, the manifestations of which closely correspond in point of time, and somewhat in character, with the lesions of similar stages in syphilis.

It will thus be readily appreciated that this controversy as to the true nature of yaws introduces difficulties into any attempt to describe the features of its osseous lesions—a difficulty which is increased by the absence or rarity of well authenticated specimens in the museums of this country.

It is in the tertiary stages of both diseases that the bones are apt to be affected and Knaggs considers that many of the accepted descriptions of the lesions in osteitis and in acute and chronic periostitis ascribed to yaws would apply equally to similar conditions occurring in syphilis. It is otherwise, however, with the epiphysitis in which the epiphyses of the phalanges and metacarpal bones are attacked, the resultant deformities of the hands and shortening of the digits being extraordinarily common.

The investigations of Maul in Manila have thrown a clearer light upon the subject. In 100 cases of yaws accurately diagnosed, bone and joint lesions

[1] "The Inflammatory and Toxic Diseases of Bone: A Textbook for Senior Students." By R. Lawford Knaggs, M.C. Cantab., F.R.C.S., Consulting Surgeon to the Leeds General Infirmary. With numerous photomicrographs by G. H. Rodman, M.D., Hon. F.R.C.S. Bristol: John Wright and Sons, Ltd. London: Simpkin, Marshall, Hamilton, Ke[illegible] and Co., Ltd. 1926.

were found in 20 of them, and in all of these X-ray photographs were taken.

In the majority numerous lesions were present, many being often met with in a single bone. These showed the rarefied areas and superficial excavations described above.

On the articular surfaces excavations appeared on those parts most exposed to injury, and Maul attributes the joint pains in yaws to them, and they possibly provide the explanation of the inflammatory joint conditions and subsequent ankylosis described by others.

A small proportion of the cases showed nodular lesions with swelling over the surface of the bone and localized thickening of the cortex, which sooner or later showed rarefaction of its centre.

In chronic conditions the picture presented by the earlier lesions of the bones disappears. There is marked irregularity of the bony outline, and growth may be interfered with when the epiphyses are affected, which occurs less frequently than involvement of the shafts of the bones.

After treatment with salvarsan the rarefied areas described by Maul rapidly disappeared and regeneration of the bone at the site of the lesions appeared to be complete. They probably constitute some of the earliest manifestations of bone implication, and it may fairly be assumed that they represent small granulomatous masses of similar nature to those which constitute the cutaneous eruption.

Knaggs considers that the multiplicity of the lesions, their widespread distribution, and the more frequent implication of the interior of the bone, present a striking picture and he confesses that he knows of nothing like this in syphilis.

A re-examination has been made by Knaggs of several bones—tibiæ and fibulæ—from New Guinea, now in the museum of the Royal College of Surgeons. They were obtained by S. C. G. Seligman from a collection of native bones from Murua and Kivaiawata, two islands near the eastern end of Papua.

He found that all these bones showed periostitic nodules, some being quite indistinguishable from syphilis. Others, however, present a curious pitted appearance of the surface of the nodes, as if associated with ulceration of the overlying soft parts. In some the upper articular surface presents the condition described by Maul, the pitting being quite different from that of syphilitic affections of the long bones. There is little evidence of syphilis among the native population of these islands, and Seligman considers that if the lesions of these bones are not due to syphilis they can only be ascribed to a disease hitherto not met with which produces similar osseous changes. He states that yaws is commonly but unevenly distributed throughout the Possession, but makes no reference to conditions constituting the tertiary manifestations of that disease. He describes, however, an *obscure* ulcerative condition ("granulomata"), and the accompanying photographs are suggestive of tertiary syphilitic ulceration, though, as Knaggs remarks, it may be that they are really examples of one of the later manifestations of yaws.

Further specimens of the bone lesions of undoubted cases of yaws are badly needed in the museums in this country and if any tropical practitioner who could do so would supply this need he would certainly assist in the advancement of knowledge in an obscure branch of tropical medicine.

F. E. T.

Annotations.

On an interesting Case of Brazilian Bubo (G. Franchini, *Il Policlinico*, January 1, 1926).—This condition was described for the first time in Italy by Breda, of Padua, it is also known as Breda's disease. It is very rare in Italy and the cases are nearly always imported by woodcutters from Brazil where many Italians are employed. Although resembling oriental sore and American leishmaniasis it is a distinctly different affection. Two cases are described: (*a*) an Italian peasant contracted the disease at St. Paulo, Brazil, where he was employed as woodcutter. It started as small nodules, the size of a pin's head, which became ulcerated, exuding small drops of a white-yellowish liquid; the ulcerations became larger and spread over large areas of the foot and legs, arms, hands, nose and mouth. There was a feeling of burning locally, but no fever or other symptoms. He was treated in the hospital of San Paulo by intravenous injections of antimony tartrate, which were well tolerated. After six or seven months' treatment the ulcers began to cicatrize. (*b*) Another case had returned to the province of Potenza, his native place, in good health. After six months he noticed severe irritation in the nasal mucosa with continuous running from the nose as if he had a cold. At the same time the uvula began to be inflamed and sore; the condition quickly got worse and the palate appeared to be covered with many white-yellowish granules. Mastication was not much hindered, but swallowing was difficult. In a nursing home in Naples he had received intramuscular injections of a thick, blackish liquid of which he did not know the name. He was partially cured. About three years later his condition became much worse and he entered the Dermo-Syphilopathic Clinic, Naples, where he was treated with intravenous injections of antimony tartrate. After fifteen days he returned home owing to the closing of the clinic, and after getting worse and with a cough he was admitted to the Colonial School of Pathology, Bologna. Besides the lesions already described, others were found on the elbows, hands, legs and feet. He was completely cured by injections of large doses of antimony tartrate and Roentgen-rays. The microscopical examination showed Leishman-Donovan parasites. The radiographic examination, in spite of the alteration in the mucous membrane of the palate, showed the bone intact, which proves that the case was one of bubo, as this disease never attacks the bones.

Reviews.

A Synopsis of the Families and Genera of Nematoda. By H. A. Baylis, M.A., D.Sc., and R. Daubney, M.Sc., M.R.C.V.S. London: Printed by order of the Trustees of the British Museum, March 27, 1926. Pp. xxxvi + 277.

The process of reorganization, which has been such a characteristic and necessary economic feature of the past eight years, has shown fruitful results in many varied directions. The medical and biological sciences have not escaped this reconstructive process and it has been very evident that a great deal of clearing up and reorientation had become necessary. In no branch, perhaps, was this more evident than in parasitology. Everyone is, of course, to some extent, conscious of much recent activity in this science, but few, probably, realize the enormous amount of progress or, at least, alteration which the past twenty years have witnessed. The result has been the accumulation of a vast amount of new knowledge and the consequent urgent need for its systematization. This need has been met to quite a satisfactory extent by the appearance of several important monographic publications, not the least valuable of which is *A Synopsis of the Families and Genera of Nematoda*, by H. A. Baylis and R. Daubney.

The authors have tackled the matter as pure systematists and, though obviously cognizant of them, have not allowed themselves to be unduly swayed by the many medical and economic aspects of the problem. Students of the medical, veterinary and agricultural sciences are thus provided with a dispassionate catalogue and an unbiased guide.

It is with a certain feeling of thankfulness that we find there is nothing very iconoclastic or irritatingly controversial in the volume. The recent mood of experimental and medical biology has been, we believe, one of conservatism, the tendency being more to preserve and improve what we already possess rather than to speculate unduly on what is to come. It has been, in fact, a period of definite stock-taking and, in accord with this, Baylis and Daubney's *Synopsis* is practically an accurate emended inventory of our stock-in-trade in this particular line.

It is a curious circumstance that, apart from its purely medical aspects, the economic and practical importance of helminthology is only just beginning to be realized in this country. Throughout the whole of last century, while helminthology, like many other branches of applied science, was struggling for recognition, the number of Englishmen who made substantial contributions to the subject was relatively remarkably small, but the past ten or twenty years have demonstrated that this country can produce first-class work on the subject which, if not so ponderous as that published on the continent in earlier years, is possibly of more immediately practical import. Baylis and Daubney's *Synopsis* will undoubtedly afford satisfaction to the academic helminthologist and be, at the same time, of real value to those who have to deal with more practical problems.

W. N.

A Manual of the Parasitology of Man. By Charles F. Craig, M.D., M.A. (Hon.), Lieut.-Colonel Medical Corps, United States Army. Illustrated. Philadelphia and London: J. B. Lippincott and Co. 1926.

This is a very fine book, being, the author states, the fruit of thirty years' experience and ten years' teaching. The important part played by protozoan parasites in human pathology is steadily becoming more widely known, and this book will play a worthy part in encouraging its still wider prevalence.

As parasites protozoa produce some of the most important and serious of human diseases, such as the malarial fevers, amœbic dysentery, sleeping sickness, kala-azar, tropical ulcer and Chagas' disease, and the present volume is heartily welcomed, seeing that it contains all the important facts that have been learned regarding the morphology, life-history, relation to disease, prophylaxis and diagnosis of these parasites, and in it is collected and included much of this information which has hitherto only been available in monographs devoted to special genera or species of protozoa.

Although containing a wealth of zoological information it is expressly denied that this manual is a zoological treatise, but is intended for the use of health officers, medical practitioners, teachers, laboratory and research workers and medical students, and each and every one of these classes of worker are warmly recommended to avail themselves of it.

One looks in these pages in vain for a description of the various pathogenic spirochætes—in fact, the words spirochæte, spironema and treponema do not appear in the index, and the same remark applies to the Rickettsia and to the organisms usually classed as Chlamydozoa. This omission is, however, intentional, for the author considers that there is at present no evidence that any of these organisms are protozoan in nature beyond the personal opinions of those who desire them to be so classed, while there is much evidence available indicating that all these organisms are more closely allied to the bacteria than the protozoa, hence the author's view that they should not be included in a work devoted entirely to protozoan organisms.

There can be very little of real importance that is known regarding the various parasites described that can have escaped discussion, whilst to prevent confusion in diagnosis descriptions of numerous freely-living non-parasitic protozoa have also been included.

The volume, which runs to 569 pages, has been well produced—well printed, well bound, well illustrated, and last, but not least, well indexed.

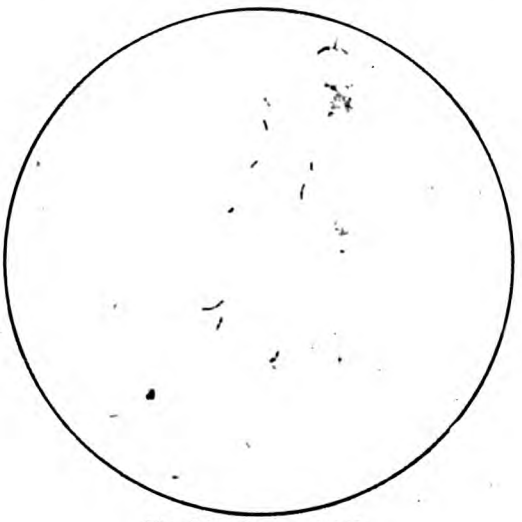
From the Ross Institute for Tropical Diseases, Putney, London.

History.

Vibriothrix zeylanica was discovered by Castellani in Ceylon in 1904 in the stools of dysentery cases, It was fully described by Castellani in 1910 under the term of *Spirillum* (*Vibrio, Vibriothrix, Spirobacillus*) *zeylanicum* in the *Philippine Journal of Science*, vol. v, No. 2, Section B; *Medical Sciences*, July, 1910. Some years later Castellani created a new genus for the organism: *Vibriothrix*. Since then this organism has been isolated in different countries. In 1917 it was found in Taranto by Castellani, Spagnuolo and Russo. In 1919, Taylor found it in London from a patient from Ceylon, who was suffering from chronic dysentery. In 1922 Delamare and Alalon found it in Constantinople. In 1923 Professor Peruzzi found it in cases of dysentery at Pola, and carried out a very complete investigation on the morphology of the organism.

Pathogenicity.

Though it has been isolated from the stools of dysentery patients, it is believed by Castellani that it does not play any part in the rôle of the disease. The organisms have been inoculated subcutaneously, intramuscularly and intraperitoneally into guinea-pigs and rabbits without any pathogenic effect unless given in massive doses. Castellani considers it to be a noso-parasite.



Examination of Fresh Preparation.

Highly motile, always polymorphic in character. The following forms may be seen in preparations from the same medium—coccus-like, bacillus-like. vibrio-like, spirillum-like, spirochætal and vibro-spirillar forms and filamentous forms. All these forms are often found in the condensation water of glucose-agar media, in the pellicle of broth and blood-broth cultures, and in the small amount of broth added to glucose-agar media.

The smaller forms are more motile than the well-formed long filamentous forms. Some of these latter are branching. The organisms which are found in the pellicle itself are less motile than those found in the liquid part of the media. Peculiar globular and club-like formations of various sizes may also be seen.

Stained Preparations.

The organism is easily stained by the ordinary aniline dyes; it is Gram-negative and not acid-fast. In preparations stained with Romanowski, the filamentous forms appear to contain deeply-stained

nuclear bodies. These have been thoroughly studied by Peruzzi.

CULTURAL CHARACTERS.

Grows in almost all the laboratory culture media at 22° C. to 37° C. It grows on potato, producing a peculiar reddish or reddish-brown pigmentation. The pellicles on the liquid media and on the condensation water of glucose-agar media are of a whitish colour. The viability of the germ remains unaffected for a considerable time at room temperature. Growth has been observed in gelatine at 22° C. and 37° C., and in blood-agar gelatine and milk and blood and gelatine at 37° C.

FILTERABILITY.

It is interesting to note that the organism, as first noted by Peruzzi, is a filter-passer using both broth and peptone water cultures. A series of experiments were made with Berkefeld candles, and *B. coli* was used as control. The results were always positive with the vibriothrix. Hanging-drop preparation of the filtrate was examined immediately after filtration under the microscope. On close observation a very few minute coccoid organisms could be seen, though with difficulty, but after half an hour the number of these organisms was found to be increased. Two or three hours after filtration, the globular forms and the bacillary forms were developed in the filtrate. Subcultures in different media showed all varieties of the organism. From this we can draw the inference that very minute coccoid bodies or spores of the organism pass through the filter; and these exceedingly minute coccoid bodies apparently give rise to the various types of organisms.

BIOCHEMICAL REACTIONS.

All the strains have been passed through almost all the important sugars. They do not split any sugar and so do not form acid; the organism produces alkalinity with some of them. It makes litmus milk distinctly alkaline, and does not liquefy gelatine or serum. It does not produce any pigmentation in lead agar.

The morphological characters and biochemical reactions of four different strains isolated in different parts of the world were studied separately. They are identical and give exactly the same reactions. The strains which have been examined by me were an Italian, an American, a Lister Institute and Castellani's original Ceylon strain.

The vibrio form is apt to be mistaken for cholera and the spirochætal form with the spirochæta.

REMARKS.

V. zeylanica, though a non-pathogenic organism, is of interest from a morphological point of view, the organism being very polymorphic, bacillus-like, spirillum-like and spirochæte-like. It also has a certain importance from the point of view of the practical bacteriologist, as the colonies of the organism on MacConkey and other selective media may easily be mistaken for dysentery bacilli colonies, and

the undulating forms observed in the fæces may be confused with spirochætes.

TROPICAL TYPHUS AND BRILL'S DISEASE.

By William Fletcher, M.D., M.R.C.P.,

AND

J. E. Lesslar, Dipl., Madras.

From the Institute for Medical Research, Kuala Lumpur, Federated Malay States.

Many a virulent disease has its milder counterpart. Such, for example, is virulent small-pox, with its milder facsimile, alastrim; the tsutsugamushi of Japan, which has a mortality of over 60 per cent., and the tsutsugamushi[1] of Sumatra which is rarely fatal; the Rocky Mountain spotted-fever of the Bitter Root Valley in Montana, which kills more than 70 per cent. of its victims, and the spotted-fever of Idaho, which is only one-tenth as deadly.

In like fashion, the dreaded epidemic typhus of Eastern Europe has its feebler image in tropical typhus, which is seldom fatal. Epidemic typhus is essentially a disease of cold or temperate climates, and when an epidemic breaks out in a hot country it usually flares up in the winter and dies down again in the spring. Tropical typhus, on the contrary, is a disease of warm climates and when it occurs in a cool country it appears in the spring and dies down in the autumn.

The symptoms of tropical typhus and of epidemic typhus are the same, both diseases run the same course and, in both, the Weil-Felix reaction is positive. Why, then, should they be looked upon as separate diseases? The reply to this question is that however closely they may be related from an academic point of view, they are totally distinct when looked at from the practical standpoint of the sanitarian and the public. The typhus of Europe is a disease which spreads rapidly and requires energetic measures for its control. Tropical typhus, on the other hand, does not spread directly from man to man; it does not give rise to epidemics: it is not carried by lice, and patients suffering from it can be treated in their houses, or in the general wards of hospitals, without special precautions and without danger to others.

[1] Described by Schüffner, in 1915, under the title of "Pseudotyphoid fever, a variety of Japanese kedani fever."

Tropical Typhus in the Malay States.

Tropical typhus was first recognized, in the Malay States, by the application of the Weil-Felix reaction in two cases of undiagnosed, continued fever where all other agglutination tests had failed. This was in August, 1925, and since that time we have met with more than eighty cases in different parts of the country; in fact, the disease is as common as typhoid fever.

As we have said, the symptoms are the same as those of epidemic typhus. The onset is sudden, usually with chills and sometimes with vomiting or an attack of sneezing. The conjunctivæ are injected and there is nearly always a dry cough. Headache is severe and persistent. The temperature rises rapidly, the severity of the headache prevents the patient from sleeping and, in a case of moderate severity, he passes into a typhoid state towards the end of the first week. He becomes tremulous, is continually muttering to himself and tries to get out of bed in his delirium; yet he can usually give surprisingly intelligent answers to questions. Delirium is present in about 35 per cent.; in mild cases there is none, except perhaps at night, but the patient's mind seems to be clouded, so that he replies to a simple question with effort and delay. The disease develops more rapidly than typhoid fever, and by the seventh or eighth day the patient's condition is more like that of a man in the third week of typhoid than at the end of the first. Sometimes the face has a blue, congested appearance in the second week and the leaden hue of the *facies typhosa* has been noticed in several European patients.

The fever is at its height from the eighth day to the eleventh day; the temperature is about 104° F. and the pulse 120. The lungs are often full of coarse crepitations and the respirations may be increased to 40 or more, even when there is little or no pulmonary involvement. The patient often looks desperately ill, but, suddenly, at the end of the second week there is a great change, the temperature falls and he becomes marvellously better. There is often a little fever for one or two evenings after the crisis, but, thereafter, the temperature remains normal and the patient makes a very rapid recovery. Defervescence usually takes place on about the fourteenth day. The fever terminates by crisis in 40 per cent. of the cases and by quick lysis in the remainder, unless it be prolonged by broncho-pneumonia or septic conditions.

The spleen and the lymphatic glands are frequently enlarged. The knee-jerks may be lost in the second week and occasionally there is slight deafness. A rash which appears on the fifth or sixth day is present in about 40 per cent. of the cases, but it is well marked and conspicuous in very few, and it is difficult to see on the skin of a dark Asiatic. In one of our European patients, a very profuse rash came out on the fifth day and covered the body with slightly raised blotches about 1 cm. in diameter; it was general in its distribution except that there was none on the face. There was not very much on the extensor surface of the arms, but the flexor aspect was thickly covered. The eruption was pro-

fuse over the trunk and thicker on the chest than on the abdomen. When we first saw this patient, on the seventh day of his illness, the rash bore a striking resemblance to the muscular eruption of secondary syphilis. It had become brown and faded by the tenth day, and some of the spots were purpuric, especially on the thighs. As a rule, the eruption is confined to the trunk, uper arms and thighs; sometimes the spots resemble the roseola of typhoid, but, in Asiatics, there is frequently no rash at all, or only a few purpuric macules.

Bronchitis is so common that it may be regarded as a symptom rather than a complication. Occasionally there is severe broncho-pneumonia. The patients are very liable to bed-sores, which are apt to develop rapidly and unexpectedly. Apart from these we have seen no complications or sequelæ and convalescence is extremely rapid.

There have been five deaths among the eighty-six cases which have come to our notice in the Malay States. We were not able to visit these five patients ourselves and no post-mortem examinations were made.

The Weil-Felix Reaction.

The Weil-Felix reaction is always positive in the tropical typhus of the Malay States, but very often it does not become so until the end of the second week . That is to say, it may be negative throughout the course of the fever and become positive only after the temperature has gone down. The titre of agglutination increases up to the end of the third week, or a little later, and then declines; it generally becomes negative in six months or less. Repeated examinations should be made in every case; the evidence of a waxing and waning titre, obtained in this way, is conclusive proof of active disease. As the result of a large number of control tests, we have adopted a serum dilution of 1 in 200 as the limit above which we regard agglutination as positive evidence; in most cases of tropical typhus the maximum titre is well above 1 in 1,000. The tests are made in Wright's pipettes with emulsions of living cultures which are prepared by washing off the twenty-four hour growth from agar slopes with distilled water. The serum dilutions are made with normal saline. The results are read after two hours in the incubator at 37° C.

The Two Groups of Tropical Typhus.

Van Loghem classified *B. proteus* in two groups: the *Indologenes* group, which produces indol in peptone water, and the *An-indologenes* group which does not. We have employed in the Weil-Felix reaction, one an-indologenic strain of *B. proteus* x 19, known as the " Kingsbury " strain, and also a number of indologenic strains. By this means, we have found that there are two groups of tropical typhus, clear cut and distinct from one another, as classified by this reaction. One group, which we will call the K group, agglutinates the an-indologenic strain " Kingsbury," but does not agglutinate the indologenic strains, such as " Warsaw " and No 67 from the National Collection of Type Cultures. The second group, which we call group W, agglutinates the indologenic strains, but does not agglutinate the an-indologenic strain. The two groups appear to be equally common, in the Malay States, and they differ but little in their course and symptoms. In neither group is there any evidence of transmission by lice.

The following tables show the Weil-Felix reaction in a Group K case and a Group W case, respectively, with the an-indologenic strain of *B. proteus* x 19, which is known as " Kingsbury " and the indologenic strains " Warsaw " and No. 67.

Group K Case.

Agglutination of Cultures of X 19 with Blood of Mengah Singh.

Culture	Day of Illness 10	16	20	36	46	62
Kingsbury	500	2,000	4,000	1,000	100	30
No. 67	0	0	0	0	0	0
Warsaw	0	0	10	0	0	0

The figures indicate the highest dilution of the serum a which agglutination took place; e.g., the figure 500 means that agglutination occurred at a dilution of 1 in 500.

Group W Case.

Agglutination of Cultures of X 19 with Blood of Narayanan.

Culture	Day of Illness 10	16	20	36	35
Kingsbury	10	10	10	10	0
No. 67	1,000	4,000	2,000	500	250
Warsaw	1,000	4,000	2,000	1,000	250

Epidemiology and Ætiology.

The tropical typhus of the Malay States has a special tendency to attack cattle-keepers and those whose occupations take them into waste land, covered with grass and undergrowth, where cattle graze. Drivers of bullock-carts, cowherds and agricultural labourers are particulary liable, and we have seen a small outbreak among some European soldiers who were encamped on waste grazing land. The town dwellers, and the Chinese who work in the tin mines of the Malay States, escape infection almost entirely.

No body-lice have been found on any of the patients and there is the strongest evidence that these insects are not the vectors. The patients do not infect the occupants of the houses or tents in which they are taken ill; moreover, though no special precautions have been adopted to free them from lice, when they are admitted to hospital, yet they never infect anyone else in the wards where they are treated. Though the disease is not contagious, in the sense that it spreads directly from man to man, it has a patchy distribution and preponderates in certain districts. In this particular it resembles the tsutsugamushi of Japan and the spotted-fever of the Rocky Mountains, diseases which are akin to typhus in many respects. Small rodents, such as field mice and rabbits, are the natural hosts of the virus of these diseases, man is but rarely infected. The virus of tsutsugamushi is carried by a larval mite and Rocky Mountain fever is carried by a larval tick. None of the patients whom we have seen

... typhus had any recollection ... by ticks or mites, but the larval ... very minute and easily escape notice. ... large numbers of rats in some of the ... cases of tropical typhus occurred in ... States and we have already mentioned ... connection of the disease with cattle. Where ... are cattle and cattle food, there are usually ... as well.

In an outbreak of tropical typhus which occurred near Adelaide, in Australia, workmen engaged in handling wheat were particularly liable to attack: in another group of cases, recently reported from Queensland, people who worked on farms, or who were employed in dealing with grain, were singled out by the disease. There was a plague of mice on the farms at the time these cases occurred, and Wheatland, who described the outbreak, considered that the virus was probably conveyed by an ecto-parasite of the mouse.

The first step in elucidating the ætiology of tropical typhus is the conveyance of the disease to animals and this we have not yet succeeded in doing, either because the patient's blood was not obtained at a sufficiently early stage, or because guinea-pigs, the only animals which we have employed so far, are not susceptible to the virus.

Tropical Typhus in Other Countries.

Tropical typhus is by no means confined to the Malay Peninsula. Similar diseases, which we believe to be identical with it, occur not only in other parts of Asia, but also in America, Africa and Australia. The symptoms and course of the typhus-like disease, in New York, which Brill described in 1898, are identical with the symptoms and course of tropical typhus. In recent years there have been many outbreaks of a similar malady, in different parts of the world, and, in nearly all of these, the Weil-Felix reaction has been positive. The following is a summary of the reports, which have come to our notice, of outbreaks of disease which we believe to have been tropical typhus.

Dr. Nathan E. Brill, professor of clinical medicine in Columbia University, was the first to draw attention to a fever of two weeks' duration, which occurred in New York every spring and summer, and which has been diagnosed and treated up to that time as abortive typhoid. In 1897 he made a special study of seventeen of these cases; he found that the blood did not agglutinate typhoid bacilli nor could these organisms be recovered from the blood or excreta. The symptoms and course of the disease, in these cases, were unlike those of typhoid fever, and Dr. Brill concluded that the so-called "abortive-typhoid" was not typhoid at all, but a distinct, acute, infectious disease of unknown origin, which hitherto had passed unrecognized.

In 1910 he published a second report, based upon the observation of 221 cases in New York. Apart from the negative Widal reaction and the absence of typhoid bacilli, the disease differed from typhoid fever in many other respects. This is clearly shown in Brill's account, of which the following is a summary: The disease began rather abruptly, with a chill; the temperature rose far more quickly than in typhoid fever and within a few days it reached its maximum. The conjunctivæ were congested, the face was flushed, and there was intense headache; sometimes there was rigidity of the neck as well, and lumbar puncture was performed in 8 per cent. of Brill's cases. Bronchitis was nearly always present. The spleen was enlarged in 54 per cent. An eruption came out on the sixth day; it appeared first on the back and abdomen and then spread to the arms and thighs. In some cases, the eruption was identical with that of typhoid fever, except that it did not come out in crops; in others, there was a dull red, maculo-papular eruption which did not disappear on pressure. The periphery of the spots was commonly indistinct and frequently several of them coalesced to form patches. In 6 per cent. the eruption was petechial, "suggesting a typhus eruption more than anything," as Brill remarked. Brill described the course of the disease as follows: "The symptoms remain in full development until about the twelfth day, when the fever abruptly disappears, the rash fades, the headache leaves, the apathy and prostration vanish and the patient feels perfectly well. . . . The most remarkable feature of this disease is that, with the fall in the fever, all the signs clear up and the patient, who may have felt and looked very sick, becomes alert, interested in his surroundings, and says he is well; the headache is dispelled as if by magic; the eruption rapidly fades, and convalescence is established." In one-third of the cases the fever terminated by crisis and the temperature became normal in less than twenty-four hours. The disease occurred principally in the summer months. There was no evidence that it was directly communicable. The case mortality was very low, probably not more than 2 per cent. There was no death among the first 220 cases reported by Brill, but shortly after his account of the disease was published there were four fatal cases.

Brill considered that this disease resembled typhus fever more than it resembled any other disease, so much so that in an epidemic he thought that it would be quite impossible to distinguish it from that malady; but, nevertheless, he concluded that it was not typhus, but another disease apart, as distinct from typhus on the one hand as from typhoid on the other. He based his argument on the following facts. It was not communicable, like typhus; it was not a grave and fatal malady; and, moreover, epidemics of it did not arise although it was constantly present in the community.

Brill's investigations drew the attention of observers in other countries to the occurrence of these mild, typhus-like fevers and, in 1910, a similar disease was reported by Smithson as occurring in the Mossman district of tropical Queensland, among labourers who worked in the sugar-cane fields. Those men who were employed in the factories were not attacked, and Smithson suggested that the disease was conveyed by some insect which lived among the sugar-cane.

In the same year, Conor and Bruch saw several

cases of fever in the environs of Tunis which, they thought, resembled Brill's disease. It began abruptly with rigors, severe headache, and a fever which lasted for fourteen days. An eruption of slightly raised macules appeared on the fifth day or earlier, the eyes were injected and the spleen was enlarged. None of the patients died.

In 1911, MacNaught described a fever in South Africa, the prominent features of which were the same as those of Brill's disease, namely, a sudden onset with intense headache, suffused eyes and a dark-red, maculo-papular eruption which came out on the fifth day and left brown stains when it faded. The fever terminated at the end of fourteen days by rapid lysis or crisis. The patients often appeared extremely ill during the first week, yet none of them died. MacNaught noted the resemblance to typhus fever, but this he excluded on account of the mildness of the disease, and because it was not contagious. He was convinced, however, that the fever which he described was the same as Brill's disease in New York.

The scholarly report which Brill published in 1910 excited considerable interest at the time. All were agreed that the disease was distinct from typhoid; but some considered that it was only a mild form of typhus, and among these was Dr. Friedman, who had considerable experience of epidemic typhus in Russia. The question was investigated by Anderson and Goldberger, in 1912, by means of animal inoculations. They succeeded in infecting monkeys by inoculating the blood of patients who were suffering from Brill's disease. When the monkeys had recovered, they were found to be immune to inoculation of the severe form of Mexican typhus known as tabardillo. Similarly, monkeys which had recovered from infection with the virus of tabardillo were immune to Brill's disease. On these grounds the authors concluded that the fever described by Brill was identical with typhus.

This argument is not very convincing; the viruses of variola and vaccinia are reciprocally protective, but they are not identical. Be this as it may, it appears to have satisfied the medical profession that Brill's disease was nothing, more or less, than a mild form of typhus, and little more was heard of it for nearly a decade.

A paper published by Colonel J. W. D. Megaw, I.M.S., in 1921, aroused fresh interest in the disease. He brought to notice a sporadic and localized form of typhus-like fever in the Kumaon district of the Himalayas which had been investigated by McKechnie some years before The symptoms and course of the Kumaon fever were like those of mild typhus or of Brill's disease. The average duration of the fever was about twelve days. At the end of this period, there was the same sudden and remarkable change for the better, followed by quick convalescence. The congestion of the face and eyes at the beginning of the fever, the extensive rash appearing on the fifth day, the mental condition, the bronchitis and rapid breathing; all these symptoms, which are the common symptoms both of epidemic typhus and of Brill's disease, were observed by McKechnie in the Kumaon fever. Where it differed from epidemic typhus was in its epidemiology; in this respect it resembled Brill's disease, for it was strictly local in its distribution and not liable to occur in widespread epidemics; it was not easily conveyed to others, and there was a pronounced tendency for the disease to attack only a single individual in a household. There was no evidence that the disease was carried by lice and it affected the well-to-do Europeans rather than the poorer natives.

More recently, Megaw, in conjunction with Shettle and Roy, reported a small outbreak at a military camp in Central India. Major Shettle saw fourteen cases in British soldiers and two in Indians. The disease did not spread direct from man to man; no other occupants of any tent in which a case occurred were attacked, and no lice were found on any of the patients.

Since Megaw drew renewed attention to this disease, or group of diseases, its occurrence has been reported in many parts of the world. In 1922, Maxy and Havers saw thirteen cases, in Alabama, of a fever with a macular rash which ran its course in two weeks. The Weil-Felix reaction was positive, and they considered that it was a mild form of typhus. There was no evidence of louse-infestation. The disease showed no tendency to spread and it resembled Megaw's Kumaon fever in its tendency to attack the well-to-do rather than the needy.

In 1923, Hone reported the occurrence of an acute illness closely resembling typhus, which had attacked a number of people who lived in and around Adelaide. The sudden onset, the rash, and the course of the malady were the same as in mild typhus or in Brill's disease, and Hone's description of the defervescence is so characteristic that we give it in his own words: "The delirium becomes marked in the severe cases and the patient looks desperately ill; then, just as one is anxious about the outcome, there is, in the majority of cases, a rapid clearing up of the toxæmia, and defervescence occurs between the twelfth and fourteenth days by crisis or rapid lysis." The Weil-Felix reaction was invariably positive in these cases. Body-lice were found on none of the patients. There was no evidence of direct infection from one person to another. Many of the earlier cases occurred among men who were working on wheat-stacks and the wharf labourers called it "wheat disease."

Typhus in a severe form, known locally as tabardillo, has been endemic in the Mexican plateau, at an elevation of some 2,000 feet, for hundreds of years; but it was not recognized in the lowlands until 1924, when Sinclair and Maxy investigated a small outbreak of mild typhus-like fever in an American cavalry camp on the frontier. Inquiries made among the medical practitioners of the neighbourhood showed that this mild form of typhus had existed for years in the Rio Grande Valley, and some of the doctors had seen hundreds of cases, about 2 per cent. of which were fatal. The fever was characterized by an abrupt onset with headache, rigors and vomiting. The temperature reached its

highest point during the first week, it became remittent in the second week, and it returned to normal about the fourteenth day, usually by lysis, but sometimes by crisis. A typhus-like eruption appeared on about the fifth day. Sinclair and Maxy investigated twenty cases; only three were seriously ill and none died. Three of them were slightly delirious, the majority were dull and apathetic. A slight cough was present in all cases. The Weil-Felix reaction was positive. A few guinea-pigs were inoculated, but they failed to show the characteristic febrile reaction, and they were not immunized against the virus of epidemic typhus. No two cases occurred in any one house; no body-lice were found on the patients, nor was there evidence of direct infection from man to man. Sinclair and Maxy consider that the typhus of the Rio Grande is the same as Brill's disease.

A similar type of fever occurs in East Africa. In 1925 Clearkin drew attention to a typhus-like disease characterized by intense headache, photophobia, prostration, and a rash which appeared on the fifth day. It has been known to practitioners in Nairobi for some years. The Weil-Felix reaction was not positive in these cases; but it was found, subsequently, that the cultures which had been used in the test had become inactive.

In 1926, Wheatland described an outbreak of a non-contagious typhus-like fever among the population of the farms surroundings Toowoomba, in Queensland. This fever resembled Brill's disease very closely; its duration was about twelve to fourteen days; it was characterized by severe headache and a macular rash, like that of typhoid, but more profuse. Defervescence took place by quick lysis or crisis. The mortality was only about 2 per cent. The disease was not carried by lice. The Weil-Felix reaction was invariably positive. There was a plague of mice on the farms in the Toowoomba district, and, in the spring, when the human disease appeared, these rodents were dying in great numbers. The farmers attributed the disease to the presence of the sick mice and they called it "mouse disease." This typhus-like fever was confined almost entirely to those who lived on mouse-ridden farms or who dealt with mouse-infested grain. Wheatland concluded that it was probably transmitted by some ectoparasite of the mouse.

In conclusion, we wish to emphasize the importance of employing for the Weil-Felix reaction not only one but, at least, two cultures of *B. proteus* x 19; both the indologenic and the anindologenic strain should be used in every case; and we take this opportunity to express our readiness to supply cultures to those of our colleagues who are interested in tropical typhus. Emulsions of living cultures should be employed, and repeated tests should be made during the third and fourth weeks, that is to say, after the patient's temperature has come down.

Comparison of Stoll and Lane Egg-Count Methods for the Estimation of Hookworm Infestation (F. L. Soper, *American Journal of Hygiene*, July Supplement, 1926).—To secure complete egg-counts between-spin stirring of the contents of the Lane tube is necessary, and the Lane count must be "pushed to finality" to be of value as a measure of the number of eggs present; this requires so much time that the method is not practical for field surveys. The Lane "pour-off" removes objectionable *substances from certain stools*, thus increasing the visibility of the eggs; there is, however, a limit to the effective concentration of hookworm eggs by the Lane method. The Stoll suspension does not secure an even distribution of eggs; the frequency distribution of repeated counts on two tubes indicates that variations in count follow the normal curve of random sampling and tend to be compensatory. In lightly infested cases the *actual error in the estimated number* of female worms present should be small, whereas, in heavily infested cases, *the percentage error in the estimated number* of female worms should be small. The Stoll method is greatly inferior to the Lane method as a measure of the rate of infestation in groups containing lightly infested individuals, but it is believed that average Stoll counts are as reliable as average Lane counts for estimating the average degree of infestation of groups containing lightly infested individuals, and are probably superior for the same purpose in groups containing heavily infested individuals. The comparative value of the two methods will depend to a certain extent on the percentage of stools of the type mentioned and the degree of infestation. Egg-per-grm. values are less variable than daily stool weights; but egg-per-grm. counts cannot be blindly accepted as measures of hookworm infestation in individual cases.

Notices.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—**All literary communications should be addressed to the Editors.**

4.—**All business communications and payments, either of** subscriptions or advertisements, **should be sent to the Publishers** of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, **which is Thirty Shillings per annum,** may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—**Special Notice.**—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to **25 reprints, free of charge.**

14.—**Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.**

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

REPRINTS.

Contributors of Original Articles will be supplied with reprints if the order for these, with remittance, is given when MS. is sent in. The price of reprints is as follows:—

	£	s.	d.
50 copies of four pages	0	16	6
100 „ „	1	3	3
200 „ „	1	6	6
50 copies beyond four up to eight pages	1	13	0
100 „ „ „	2	6	0
200 „ „ „	2	17	6

Postage extra according to weight.

One page of the Journal equals 3 pp. of the reprint.

If a printed cover is desired the extra cost will be, for 50 copies, 13/9; 100 copies, 19/6; 200 copies, £1 12s. 6d.

THE JOURNAL OF

Tropical Medicine and Hygiene

NOVEMBER 15, 1926.

MALARIA IN WOMEN.

ALTHOUGH there would appear to be no sex incidence in malaria, the sexes suffering equally when equally exposed to infection, yet there cannot be the slightest doubt that malaria affects the normal functions of the sex-organs of women in ways that are varied and far-reaching and also exerts marked modifying influences on the course of pregnancy and the puerperium as well as on the diseases peculiar to women.

In considering the effect of malaria on the normal functions of the female generative organs, we cannot ignore the influence of climate on menstruation in the tropical countries in which malaria is most abundantly encountered.

Again, the direct effect of malaria on the female generative organs needs much investigation for its further elucidation. Severe malarial infections in young girls undoubtedly delay both general and sexual development. A condition of infantilism and retardation of puberty may result so that the onset of menstruation is delayed. A small, underdeveloped uterus has been found in some of these cases.

Montèl and Dan Van Cuong have recorded two cases in Annamese girls of eighteen years of age whose development was so retarded by malarial cachexia that they resembled children aged ten years. After the administration of quinine not only did the malaria symptoms clear up, but development commenced to proceed normally and menstruation appeared in due course.

When the malarial infection is contracted after puberty has been established menstruation tends to become scanty and irregular, and complete amenorrhœa is usually present in malarial cachexia. Whether the amenorrhœa in malaria is due to the direct action of toxins on the genital organs or to their indirect action on the endocrine glands cannot be stated, though it would appear that both these conditions may contribute to the result.

It may be said, in general, that as a consequence of any acute general infection there may ensue a period of amenorrhœa, with atrophy of the ovaries, uterus, external genitals and breasts. This, however, is usually a temporary manifestation unless there has been some specific destruction of the ovarian follicles, and it generally disappears when the patient has regained her normal health and strength.

Malaria may also be the cause of metrorrhagia, and it has been observed that the metrorrhagia may share in the periodicity of the disease appearing at a certain time each day.

In the treatment of malarial amenorrhœa the malaria should be energetically treated by the regular systematic administration of quinine followed by the use of iron and arsenic in some easily assimilable form as soon as the malarial symptoms have disappeared.

In considering the effect of malaria on pregnancy and of pregnancy on malaria it may first be noted that sterility is frequently encountered in malaria, which is said to lessen sexual power.

Pregnancy was formerly considered to confer some degree of immunity against malaria, but it is now more generally held that pregnancy *per se* has little or no influence on malarial infection, but that pregnant women are, as a rule, less exposed to

infection. Again, latent malaria is prone to make itself manifest towards the close of pregnancy and in the puerperium

Abortion or premature labour is very apt to occur and the position was summed up by Manson in these words: "Malarial fever is likely to end in abortion unless treated by quinine; if treated by quinine pregnancy culminates in a successful issue, *ergo*, quinine should always be given in malaria in pregnant women." In this opinion he is supported by Goth, who has reported that nineteen out of forty-six cases ended in premature labour, and by Edmonds, who states that this accident is very common in Africa.

On the other hand, Whitridge Williams says that despite the somewhat widespread opinion to the contrary it would appear that the ordinary forms of malaria have but little influence on the course of pregnancy. None of his fifteen cases aborted, and in but two did pregnancy end prematurely and then only a week or so before term. He admits, however, that it is possible that the pernicious forms of malaria may have a much more deleterious effect. There is also, he states, a marked tendency toward recrudescence of the disease during pregnancy and the puerperium just as is frequently observed after surgical operations. As regards the use of quinine Williams believes that it should be administered unhesitatingly to women suffering from malaria during pregnancy, as its oxytoccic powers are apparently in abeyance under such conditions, so that it can be used with impunity without fear of setting up uterine contractions. During the puerperium malaria usually presents atypical symptoms often resembling those of sepsis, so as to simulate puerperal fever, though it should not be very difficult to differentiate the two. They may, of course, co-exist in the same patient, when the diagnosis is by no means simple.

Puerperal eclampsia is said to be more common in malarial districts than elsewhere. Subinvolution of the uterus and post-partum hæmorrhage are also common accompaniments of puerperal malaria.

Malarial mastitis, too, is sometimes encountered and generally ends in resolution. Lactation is apt to be difficult and there may be actual suppression of the milk secretion.

As to the fœtus itself, it may also suffer from malaria, but there still seems to be no consensus of opinion as to the possibility of placental transmission of the plasmodium from the mother to the child with the production of true congenital malaria. F. E. T.

Annotations.

A Case of Infection with Lagocheilascaris minor (Leiper) (J. L. Pawan, *Annals of Tropical Medicine and Parasitology*, June 24, 1926).—Specimens of the worms obtained from the tumour mass and the tonsil, transmitted to Professor Leiper were identified as *Lagocheilascaris minor*, and were first described by him in 1909 in cutaneous abscesses in Trinidad, and have since been found by him among specimens received from Dutch Guiana.

Modifying the Course of Infections with Bird Malaria by Changing the Sugar Content of the Blood (R. W. Hegner and M. S. MacDougall, *The American Journal of Hygiene*, July, 1926).—There seems to be no doubt from the data obtained that an increase in the sugar content of the blood modifies the course of the infection, bringing about conditions favourable for the parasite, and hence prolonging the infection until death results. According to certain hypotheses, decreasing the sugar content of the blood should bring about unfavourable conditions for the parasite. Attempts to do this with insulin have been made with suggestive, but not conclusive, results.

Is the Formation of Guarnieri Bodies an Exclusively Mammalian Response to Infection with the Vaccine Virus? (H. B. Andervont, *American Journal of Hygiene*, July, 1926).—So far as the formation of cell inclusions in the rabbit is concerned, these conclusions bear out those of Kadowaki. Neither in the cornea nor in the skin were any structures found following the inoculation of the epithelioma contagiosum virus (poultry pox virus) which even remotely bore any resemblance to either the Bollinger bodies or the Guarnieri bodies, while the latter appear uniformly and typically following inoculation of the vaccine virus.

Animal Infections with the Trophozoites of Intestinal Protozoa and their Bearing on the Function of Cysts (R. W. Hegner, *American Journal of Hygiene*, July, 1926).—Trophozoites of certain intestinal protozoa may pass unharmed through the anterior portion of the alimentary canal and apparently may set up infections in the regions where they are normally localized, but that this probably is not the usual method of infection in nature. The cyst stage is, therefore, the dangerous stage so far as the transmission of these protozoa to new hosts is concerned, and efforts for prevention and control should be directed as heretofore toward this stage in the life history of the organisms.

New Data on Differential Fertility in the United States (Raymond Pearl, *American Journal of Hygiene*, July, 1926).—In the American population it appears that the professional, clerical, trade, domestic and personal service, public service and transportation occupational classes are reproducing themselves in such manner as to maintain about in its present status their relative representation in the population. The heavy labouring classes—manufacturing, agriculture and mining—are reproducing themselves greatly in excess of their representation in the population; they not only have a higher proportion of more fertile families per unit of population so occupied than do the other occu-

pational groups, but also they have a larger average number of children per family. The racial, social and economic significance of these results will be discussed in a further paper.

Relationship of Plankton to Anopheline Larvæ (L. T. Coggeshall, *American Journal of Hygiene*, July, 1926).—Larvæ dissections were carried out to determine whether the anopheline species exhibit preference for certain types of food. The three species examined showed no discrimination in their selection of food. Repeated observations on the food materials available in the various breeding places indicated that the larvæ adapt themselves to the food supply of the water in which they find themselves. The adult female may show some discrimination in selecting a place in which to lay her eggs, having been attracted to it by the plant odour emanating from it. It is impossible to say whether or not the eggs of some species are laid in unaccustomed places where larvæ perish before reaching maturity. It would seem that the latter is not the case.

Studies on the Ætiology of Epidemic Encephalitis. I. The Streptococcus (A. C. Evans and W. Freeman, *Public Health Reports*, June 4, 1926).—A pleomorphic streptococcus highly virulent for rabbits when inoculated intracerebally was obtained from the nasal washings, heart blood and mesencephalon of a case of epidemic encephalitis. In so far as the comparative tests have been made, this streptococcus agreed with the streptococci obtained from cases of epidemic encephalitis by Von Wiesner and by Rosenow. Apparently several other investigators have cultivated the same organism in their studies of the disease. When inoculated intravenously into rabbits the streptococcus shows a tendency to elective localization in the brain. In rabbits and in monkeys it produces nervous symptoms which in some cases simulate the disease in man. Rabbits inoculated with this streptococcus show no inflammatory lesions outside the central nervous system. The meninges are heavily infiltrated with lymphocytes and leucocytes, the inflammation spreads to the cerebral substance by direct extension and along the small vessels penetrating into the brain. There are severe parenchymatous degenerative changes in the nervous tissue and reaction of the neuroglia. The sheaths of the blood-vessels are infiltrated by lymphocytes. The reaction is sometimes most marked in this mesencephalon. In monkeys there is a greater tendency towards leucocytic reaction, and in two instances large areas of hæmorrhagic inflammation in the basal ganglia were noted.

Comparison of the Potency, Polyvalency and Therapeutic Action of Antimeningococcus Serums (A. Wadsworth, M.D., and M. B. Kirkbride, *The American Journal of Hygiene*, July, 1926).—Further experience confirms the conclusions of previous papers that in the absence of any method of titrating toxin-antitoxin neutralization in antimeningococcus serum, the agglutination test is the simplest, most satisfactory and practical method of standardizing these serums when standard cultures, representative of the recognized groups of meningococci are used with a standard serum for purposes of comparison. There is no evidence of lack of therapeutic potency or polyvalency in serums possessing the high agglutinative activity with these cultures. Failure of a recently isolated meningococcus culture to agglutinate in a serum is not necessarily indicative of lack of therapeutic potency. The immunization of horses with six selected representative strains apparently produces serums of higher titre and polyvalency than with a larger or smaller number of strains. Both the titre and the polyvalency may be sacrificed by the addition of too large a number of strains. On the whole, the results of serum therapy in the series of cases reported in this paper show an unusually low mortality, despite the unfavourable conditions under which many of the cases were treated. A few cases did not respond to treatment; a few reacted favourably and then, suddenly, fatal conditions developed in the meningeal processes of the central nervous system or in the course of some complicating secondary infection. The importance of early diagnosis and prompt serum treatment is confirmed, but striking results were recorded in some of the cases treated late in the course of the disease.

The Neoplastic Nature of Lymphatic Leucæmia and its Relation to Lymphosarcoma (W. A. Evans and T. Leucutia, *The American Journal of Roentgenology and Radium Therapy*, June, 1926).—Three cases of lymphosarcoma are described which in their terminal stages changed into lymphatic leucæmia. These three cases are the only lymphosarcomata in a group of sixteen patients treated by deep Roentgen-ray therapy during the last four years, which had a fatal termination. In all three cases radiation therapy produced prolongation of life with entire disappearance of the manifest lesions treated, but later extension of the bone-marrow occurred. At the time of the bone-marrow involvement, all three patients had developed the picture of lymphatic leucæmia. Evidence is thus brought that lymphosarcoma, if life is sufficiently prolonged, may change into lymphatic leucæmia. This happens as soon as the bone-marrow involvement becomes the predominating feature of the disease.

Epidemiological Consideration of the Transmission of Kala-azar (L. E. Napier, *Indian Medical Research*, February, 1926).—There is considerable evidence in favour of the hypothesis that man forms an essential link in the endless chain of kala-azar transmission, but the hypothesis is not proven. There is very strong evidence that the disease can-

not be spread without the aid of an intermediate host. The transmitter is probably a blood-feeding arthropod; on epidemiological grounds only it seems most probable that it is a member of either the genus *Phlebotomus* or the genus *Culicoides*. In the case of most arthropods which have been suggested as possible transmitters of the disease there are numerous epidemiological observations which negative the suggestions, but in the case of *Phlebotomus argentipes* every single epidemiological observation seems to be in keeping with the theory that this insect is the transmitter of the causative organism of kala-azar. Although it is possible that at some future date our knowledge of the geographical distribution and habits of other species of arthropod may point to still other possible hosts, at the present time on epidemiological grounds *Phlebotomus argentipes* can claim the first place in the list of possible transmitters of kala-azar. The obtaining of a more exact knowledge of the distribution of *Phlebotomus argentipes* in the Indian Empire appears to be a most important step towards proving that this insect is the transmitter of kala-azar in India.

Studies on Oral Infection with Ankylostoma (S. Yokogawa and T. Oiso, *American Journal of Hygiene*, May, 1926).—When the mature larvæ of *Ankylostoma caninum* are given to guinea-pigs, rabbits or mice *per os*, most of them penetrate the wall of the alimentary canal and migrate to the lungs through the blood-stream and lymphatics in the same way as following skin infections, and from there go into the alimentary canal via the bronchi, trachea, larynx, pharynx and œsophagus. Some of the larvæ ingested by these animals may first migrate into the abdominal cavity, boring through the wall of the alimentary canal and from there penetrate the liver or into the pleural cavity and the lungs and then take the migratory course, as above, to the alimentary tract. On the other hand, when the mature larvæ of *A. caninum* are given *per os* to the proper host, the dog, they generally do not travel in the body of the host, but grow in the alimentary canal without any such migration. The fact, therefore, that in the case of skin infections the larvæ pass through the lungs has no special connection with the development, nor with the acquisition of resistance against the digestive juices, but is, one might say, a case of *force-majeure*, the larvæ being inevitably carried or guided there by the blood or lymphatic stream.

An Occupational Disease among Zinc Workers (C. P. McCord and A. Friedlander, W. E. Brown and D. K. Minster, *Archives of Internal Medicine*, May 15, 1926).—In a small galvanizing plant, the authors have detected widespread gastro-intestinal conditions, varying from gastro-enteritis, in the younger workers, to well-established gastric and duodenal ulcers among workers employed for a long time. Twelve out of fifteen workers employed seven years or longer have presented severe gastro-intestinal lesions. In a second plant, in which all employees were new at this work (less than six years) and in which the general work conditions are better and exposure to trade process fumes is much less, no cases of this gastro-intestinal disease were found. The authors have shown the accidental formation of zinc sulphate and zinc chloride at levels and under conditions that involve exposure on the part of the workers in the first-mentioned plant. In all workers whose urine has been tested, zinc has been found in quantities in excess of the accidental urine content from food, galvanized iron pipes, &c. These patients have not presented the characteristics of other occupational disease hazards attending galvanizing. The authors have sought to stress the occurrence of multiple hazards in the galvanizing industry. On this account it is felt unwarranted in drawing any precise conclusions as to the ætiologic factor in these cases. Although one attaches significance to zinc as a causative agent various other substances are accepted as possible contributing factors. It is also believed that the unhygienic conditions of the workplace, together with the physical type of worker, favour the occurrence of the conditions described. A close resemblance is seen between the authors' observations of lesions among zinc workers and the findings in the literature referred to by them in which study has followed the administration of single, chemically-pure substances. The concept that zinc is capable of producing chronic systemic poisoning is aided by the work of several authors establishing stored zinc in appreciable quantities in various organs and tissues and in excreta of zinc workers, long after the discontinuance of zinc work; by the creation of alimentary tract lesions by pure zinc salts administered intravenously and by mouth. A long period of time, expressed in years (from five to twenty), appears necessary for the production of the lesions described.

The Morphology and Cultivation of Embadomonas cuniculi (n.sp.) (J. Collier and W. C. Boeck, *The Journal of Parasitology*, March, 1926).—*Embadomonas cuniculi* (n.sp.) is an uncommon parasitic flagellate of rabbits; it was found in the cæcum of only two out of more than fifty rabbits examined. It is ovoid in shape, averaging 9·5 by 5·5 microns. It possesses a cytostome with chromophilous, rigid lips; an anteriorly situated nucleus with a central karyosome connected by a rhizoplast with the centrosome on the nuclear membrane; and two flagella, one a long thin anterior flagellum and the other a shorter and thicker cytostomal flagellum, each arise from a separate blepharoplast. The grape-seed shaped cysts measure 5 to 6·5 microns by 3·5 to 4 microns. They contain a central nucleus and the cytostomal fibre and both blepharoplasts of the motile organism. Division occurs by binary fission, with the nucleus passing through the various stages of mitosis. The plane of plasmotomy is morphologic-

ally longitudinal. *E. cuniculi* was cultivated in Locke egg-serum (L.E.S.) medium, both at room temperature and at 37° C. The cultures at room temperature lived longer. Attempts to cultivate *E. cuniculi* in a medium such as is used for the growth of free-living non-parasitic protozoa resulted in failure and demonstrated that this organism is a parasite (commensal). Attempts to infect young chicks with *E. cuniculi* indicated that since the chicks were infected for only a short time they could not serve as proper hosts for this flagellate. This seems probable also in the case of the rat.

Gastric Secretion in Diabetes Mellitus. Report of Ten Diabetic Patients who had Diarrhœa and Achlorhydria (B. D. Bowen and A. H. Aaron, *Archives of Internal Medicine*, May 15, 1926).—Fractional gastric analyses have been made on sixty-nine diabetic patients. On critical analysis this group cannot be considered as strictly representative of diabetes as it would be seen in a large group of cases, because of the inclusion of a number of patients who were studied some time before on account of diarrhœa, and also because the majority were hospital cases, which are possibly more severe than the average. A complete absence of free hydrochloric acid was found in twenty patients, or 29 per cent. Of these, ten had diarrhœa, while no cases of diarrhœa were found in which the patients had free hydrochloric acid. The artificial use of dilute hydrochloric acid did not appear to affect the diarrhœa in four patients, three of whom died, one having marked steatorrhœa. In the other six patients, the diarrhœa stopped coincidenly with the use of the acid, but did not reappear when the acid was withdrawn. The patients, however, in all instances took the acid over a period of several months. There was no reappearance of free hydrochloric acid in one case that was subsequently studied. Of the twenty patients who had achlorhydria, the average duration of the diabetes was 6·5 years and diabetes was severe in every case at the time of observation. The duration in the normal group was 2·8 years, while the gastric subacidity group held the middle position, with an average of 3·6 years. There was no essential difference in the average ages of the patients in the three groups. In an analysis of the complicating factors in each case, it does not appear that the conditions that are known to produce achlorhydria in non-diabetic subjects are more prevalent in the achlorhydria group. From the result of these observations it seems justifiable to presume that achlorhydria may be the result of long standing or severe diabetes.

Cultivation of Trichomonas, Thermal Death-Point Anaerobic Conditions, Attempts at Sterilization (J. M. Andrews, *The Journal of Parasitology*, March, 1926).—The serum-saline-citrate medium has proved to be the most satisfactory medium for the cultivation of certain trichomonas. Saturation of the medium with oxygen or carbon dioxide has no significant effect on the growth of the flagellates. Cultures remain positive twice as long when covered with paraffin oil. *Pentatrichomonas ardin-delteili* grows better in a medium containing 2 per cent. of human blood-serum than in one containing greater amounts. It does not multiply in a medium containing 10 per cent. of human blood-serum. Room and ice-box temperatures are both unfavourable. *Trichomonas muris* gave similar results when inoculated into media containing rat blood-serum. *P. ardin-delteili* grew better in a medium containing rat serum than in media containing sera from man, rat, rabbit, guinea-pig or monkey. *T. muris* grew best in a medium containing monkey serum. The addition of dextrose brought about an increase in the number of *T. muris* in the culture and also a prolongation of the life of the culture. *P. ardin-delteili* did not survive in culture media containing 75 per cent. or more of nutrient broth. Nutrient broth in lower percentages was not favourable for the cultivation of this species. Trichomonas from man, monkey and rat grew as well in media containing sterilized Löffler's inspissated blood-serum as they did when this serum was not sterilized. *Thermal death-point*: Trophozoites of the seven species of trichomonads studied were killed at a temperature of 49° C. *Anaerobiasis*: Trichomonas of the five species studied lived and multiplied under conditions which indicate that they are facultative anaerobes. *Sterilization of cultures*: Attempts were made to free trichomonas cultures from bacteria by the following means: washing, dilution, mechanical obstacles and traps, fresh egg-white mercurochrome, butyl and butylyl resorcinol. Eventual success will probably be obtained by combinations of these methods, especially with the aid of filtration, which gave the best results.

Further Observations on the Transmission of Cutaneous Leishmaniasis to Man from Phlebotomus papatasii (S. Adler and O. Theodor, *Annals of Tropical Medicine and Parasitology*, June 24, 1926).—The infection rate of sandflies with Herpetomonas in Jericho was found to be about one per thousand during 1925. The morphology of naturally occurring Herpetomonas in *Phlebotomus papatasii* is described. Two out of three experiments in transmission of cutaneous lieshmaniasis from sandflies naturally infected with Herpetomonas were successful. Sandflies were artificially infected with *H. tropica* by feeding on oriental sores, 10 per cent. of the sandflies being infected. Attempts to transmit oriental sore to seven volunteers by eleven inoculations with material from sandflies artificially infected with *H. tropica* were all negative within an observation period of three and a half to four months.

Studies on the Epidemiology of Scarlet Fever (A. S. Pope, *American Journal of Hygiene*, May, 1926).—On the basis of attack rates, the age dis-

tribution of scarlet fever cases in Providence corresponds closely to that usually described in American cities. The greatest incidence is at 6 years. Approximately 75 per cent. of all cases occur under 10 and 90 per cent. under 15 years. The highest mortality in scarlet fever precedes the mode of morbidity and occurs in the third year of life. This is explained by the distribution of case fatality, which is highest during the first year and relatively low after the fourth year. In Providence 52 per cent. of all deaths occur under 5 years, and 80 per cent. under the age of 10. In the past forty years there has been a relative shifting of mortality from the lower to the higher age-groups. Attack rates in Providence show a slight excess among males up to the sixth year of life and at all ages above 7 a marked excess among females. This apparent difference in the susceptibility probably depends upon two factors, viz., a physiological difference in susceptibility of the sexes at different periods of life, and increased exposure among females, especially in the higher age-groups. A similar ratio is noted in the mortality rates, but the excess among males under 5 is more noticeable. For all ages the case fatality rates are about 20 per cent. higher among males. Although varying in different years from October to June, the month of greatest incidence for scarlet fever is usually January. In all but three years out of forty the minimum incidence has occurred in July or August. The seasonal distribution of deaths differs but little from that of cases, but is less well determined. Case fatality fluctuates considerably from month to month, but shows no evidence of trend or definite seasonal variations. There has been no appreciable change in the recorded morbidity of scarlet fever in Providence or in American cities as a whole during the past 40 years. In Providence attack rates have remained practically constant in all age-groups except in infants, where a significant downward trend is apparent. No evidence of periodicity in the incidence of scarlet fever can be seen in the Providence figures nor in the morbidity data from some fifty large American cities for the period 1890-1920. While the morbidity of scarlet fever has remained practically constant since 1885, the mortality rates in Providence have fallen from approximately 40 to 2 per 100,000. The decline has been equally remarkable in most American cities. Where scarlet fever in Providence formerly was responsible for 5·3 per cent. of all deaths it is now the recorded cause of only 0·3 per cent. of total deaths. That this fall in mortality is due to decrease in malignancy of the disease seems probable on the evidence available. There is no reason to assume that control measures have been appreciably responsible for this decline in the mortality of scarlet fever. The decline in case fatality has been practically as great as that in mortality. This is especially marked in the age-groups under five. Case fatality may or may not be higher in eipdemic years and there is no evidence of a significant correlation between case fatality and morbidity rates. Among 22,000 cases of scarlet fever, 271 were recorded as second attacks. It seems probable that this is an under estimate of the percentage of recurrence of scarlet fever in the individual. That one attack does confer a relative immunity is indicated by the fact that only 14 per cent. as many cases were recorded among those who previously had the disease, as among the general population. A marked preponderance of females in the higher age-groups among recurrences is further evidence that infection with scarlet fever depends to a great extent upon the intimacy of contact with cases. Although secondary attack rates in the family vary widely from year to year, there is no significant correlation between such rates and the general prevalence of the disease in Providence. That is, there is no evidence that the disease is in itself more infectious in epidemic than in non-epidemic years. The epidemic curve of the scarlet fever, as determined by the outbreak of 1923-24 in Providence, is essentially a normal distribution.

Observations on the Development of Hookworm Larvæ (P. A. Maplestone, *Annals of Tropical Medicine and Parasitology*, June 24, 1926).—This series of experiments shows that urine has definite effect in destroying both hookworm eggs and freshly-hatched larvæ. It has been noted that it is somewhere between nine and fourteen days before all the hookworm eggs in fæces are killed by urine. In one experiment the eggs must have been in a condition to hatch out, so it must be assumed that urine-moistened soil will kill young larvæ. Miniagawa, working with *Ankylostomum caninum*, showed indirectly that urine killed the larvæ of this species, for he failed to infect young dogs that were placed on soil that had been heavily infected with fæces containing eggs of *A. caninum* and which had been moistened with urine previously, whereas in his control experiments the dogs became infected. The inference drawn by Minagawa was that the larvæ of *A. caninum* were killed by contact with human urine, and the writer's experiment shows that the same applies to the larvæ of hookworms infecting human beings. In another experiment it was seen that the packets of fæces were only partly submerged in water, and the result was that after five weeks there was no dearth of hookworm eggs; in another, however, in which the fæces were totally excluded from contact with air, all the eggs failed to hatch after the same period of immersion. Khalil found apparently normal undeveloped hookworm eggs in the effluent septic tanks of British Guiana and he concludes that septic tanks of the type investigated are of no use in preventing the spread of ankylostomiasis except by concentrating the infective material into one channel. As there was apparently no way of knowing how many eggs entered the tanks it is not possible to say if any were killed during their passage through the system The present series shows that after four days' complete immersion in water about 25 per cent. of the eggs were destroyed, and there is a steady diminution in the number of viable eggs recoverable from water as immersion is continued, until after a period

of five weeks all the eggs seem to be dead. From these observations it seems safe to conclude that septic tanks would have some effect in reducing hookworm infection, the actual reduction being directly dependent on the time the fæces remained in the tank.

Meningitis due to Bacillus enteritidis Gaertner (G. Stuart and K. S. Krikorian, *The Journal of Hygiene*, July, 1926).—It would appear that only nine cases of meningitis have been traced to the paratyphoid group of organisms: seven to *B. paratyphosus* B, one to *B. paratyphosus* A and one to a bacillus of undifferentiated type. The case here described is unique in so far as no reference has been found in medical literature to meningitis due to *B. enteritidis* Gaertner. The patient was a boy of eleven years, residing in Jerusalem. He was sent to the hospital as a case of enteric fever, but was found to be suffering from symptoms of meningitis, and later passed into a state of complete coma which lasted until his death fourteen days after entering hospital. Agglutination tests showed the organism to be of the type *B. enteritidis* Gaertner with fully developed labile antigen; it possessed labile and stable receptor apparatus identical with those of typical *B. enteritidis* Gaertner.

A Second Case of Sleeping Sickness in the Sudan caused by Trypanosoma rhodesiense (R. G. Archibald and D. Riding, *Annals of Tropical Medicine and Parasitology*, June 24, 1926).—The clinical history of this case of human trypanosomiasis and the morphological characters of the trypanosome in the blood of rats inoculated with the gland juice of the patient, supports the view that this was a case of human trypanosomiasis caused by *T. rhodesiense*, a hypothesis which received further confirmation by testing the pathogenicity of the trypanosome in the white rat, gerbil, monkey, rabbit and guinea-pig. The posterior nucleated forms were not found in the gland juice of the patient, but appeared in an unusually high percentage in the blood of inoculated rats, constituting nearly 20 per cent. of the short broad forms of the trypanosomes in the first series of inoculated rats. Sub-inoculations carried out in these animals showed that the posterior nucleated forms averaged from 5 per cent. to 13 per cent. of the short broad forms, the percentage varying with the duration of the infection in the inoculated rats. The previous record of *T. rhodesiense* in the Sudan (1922) was a case of human trypanosomiasis in a native of the same district of the Bahr el Ghazal; gerbils inoculated with the gland juice from this case showed the presence of posterior nucleated forms in peripheral blood-films, these forms occurring also in subinoculated white rats and a dog. The measurements of the trypanosomes were very similar to those of the second case, varying from 10 to 30 microns. The pathogenicity of the trypanosome from the two cases resembles that of *T. rhodesiense*. The two cases are of interest inasmuch as they occurred in natives of the Tembura district of the Bahr el Ghazal, a sleeping sickness area in which *T. gambiense* is endemic and in which the tsetse-flies *G. fuscipes* and *G. morsitans* abound. Thanks to the energetic and successful measures for dealing with sleeping sickness, the malady in the Bahr el Ghazal appears to be under control, but the danger of infected cases crossing the western frontier from adjacent territories is a real one, necessitating close co-operative measures with the countries concerned. So far, the common form of human trypanosomiasis has been caused by *T. gambiense*, but the authorities are fully alive to the possibilities of *T. rhodesiense* occurring in man in a country where *G. morsitans* is almost ubiquitous and where game and stock act as reservoirs of *T. pecaudi* vel *brucei*. The two cases reported indicate so far that human trypanosomiasis caused by *T. rhodesiense* exists in the Bahr el Ghazal only in sporadic form.

The Clinical Value of Hay's Sulphur Tests for Detecting Bile Acids in the Urine (W. I. Gerrard, *Journal of the Royal Naval Medical Service*, July, 1926).—Hay's sulphur test is very simple and is of much clinical importance in investigating the relative excretion of bile-salts and bile-pigments. It is of particular interest in the study of salvarsan and dissociated jaundice. The modified technique should be used. The reaction of the urine and its specific gravity do not in any way affect the accuracy of delicacy of the test. Compared with Pettenkofer's test the delicacy of Hay's reaction is marked. The many fallacies in applying Pettenkofer's test render it almost useless; one part of bile-salts in 1,000 gives only a doubtful reaction. The causes of error in interpreting Hay's test are easy to avoid. The test reveals the presence of bile-salts in slight liver lesions hitherto unobserved. A haphazard technique in the use of Hay's sulphur test will lead to entire failure to recognize cases in which bile-salts are present in the urine in small amount.

The Estimation of the Number of Hookworms harboured, by the use of the Dilution Egg-Count Method (R. B. Hill, *The American Journal of Hygiene*, July Supplement, 1926).—In order to check the suggestion of Stoll that the factor 44 represents the average egg output per grm. of fæces per female hookworm, and that such a factor can be used to estimate the number of parasites when only eggs per grm. are known, the total egg output of 96 heavily infested cases was estimated for two or three days and compared with the number of worms recovered after treatment to a cure. A positive correlation was found between each of the items: the total daily egg output, the number of eggs per grm. basis formed, and the number of female hookworms harboured. The calculation resulted in finding that the factor 18·3 represented the number of eggs per grm. per female in this series. This factor, when

applied to the egg-counts in a series gave a close estimate of the number of female hookworms harboured, but when applied to the other groups was usually too low. Stoll's proposed factor of 44 was too high. It was found that fæces recovered could be classified as formed, soft, or mushy, and that the average amounts of these classes, per day, were 147, 226 and 314 grm. respectively, a ratio approximately 1 : 1·5 : 2. It is suggested that for comparison all counts per grm. be reduced to the basis of formed stools by the use of the proper factor. As the number of worms harboured increases, the egg output per worm decreases.

The Proportion of Viable Bacilli in Agar Cultures of Bacillus aertrycke (Mutton) with special reference to the change in size of the organisms during growth, and in the opacity to which they give rise (G. S. Wilson, *Journal of Hygiene*, July, 1926).—Working with agar cultures of a strain of *B. aertrycke* (Mutton) it was found that the number of organisms requisite to cause a given opacity was five times as great in a 26-hour as in a 4-hour culture. This difference is probably explicable by the fact that bacilli from young cultures are larger than those from old ones. Evidence is produced which suggests that the opacity method gives a measure not of the number of organisms but of the total quantity of bacterial protoplasm in the suspension. It should therefore be of special value in the standardization of vaccines. It is pointed out that the opacity method when used for the enumeration of bacteria is subject to a considerable error, and is hence unsuitable for accurate work. A technique is described for the estimation of the proportion of viable to total organisms in an agar culture. The results obtained are closely similar to those already described for broth cultures. The maximum proportion of living bacilli is reached at the end of the logarithmic phase of growth, where about 80 per cent. of the organisms are alive and capable of reproduction. It seems probable that there is a mortality amongst the bacilli that are generated in the early stages of growth, the least resistant organisms failing to divide.

Reviews.

SOME DEVELOPMENTS OF HARVEY'S DOCTRINE "OMNE VIVUM EX OVO": being the Harveian Oration delivered before the Royal College of Physicians of London on October 19, 1925. By Sir Frederick Mott, K.B.E., M.D., LL.D., F.R.C.P., F.R.S. (Consulting Physician, Charing Cross Hospital, London). John Bale, Sons and Danielsson, Ltd. London. 1925.

This learned and eloquent oration by the late Sir Frederick Mott deals chiefly with the evidence of heredity in certain types of mental disease, especially dementia præcox, and with the part played by heredity in the ætiology of mental disease. He discusses also the tendency there is to end or mend a degenerate stock. A select bibliography concludes the brochure.

THE HEALTH OF THE WORKERS. By Sir Thomas Oliver, M.A., M.D., D.Sc., LL.D., D.C.L., F.R.C.P., Professor of the Principles of Medicine, University of Durham. Faber and Gwyer, Ltd. (The Scientific Press). London. 1925.

This small volume is one of the series of Modern Health Books edited by Professor Fraser Harris, which are designed to bring within the reach of everyone the latest expert opinions on the chief problems of health. Sir Thomas Oliver has written the book to meet the growing interest taken by the public in medical and social problems connected with industrial occupations and has accordingly avoided using too technical language. He has, nevertheless, provided much useful information which cannot fail to interest medical men also, and which bears the personal impress of a great authority on the subject of industrial hygiene.

REPORT TO THE SECRETARY OF STATE FOR THE COLONIES ON THE OUTBREAK OF PLAGUE IN THE GOLD COAST COLONY AND ASHANTI. By Professor Sir William Simpson, C.M.G., M.D., F.R.C.P., D.P.H. Published by the Crown Agents for the Colonies. 1925.

Sir William Simpson points out that until the first quarter of 1924 there had been no serious outbreak of plague since 1908, when there were 344 recorded cases in the colony, of which 300 were fatal. Of the fatal cases, 157 occurred in Accra and its neighbourhood. From 1908 to 1917 the Gold Coast was free of plague. In January, 1917, plague appeared at Ofako, in a village nine miles from Accra, and 39 deaths were traceable to this source. Unlike that of 1908, there was no obvious association with an epizootic of plague among rats. In December, 1917, nine deaths from pneumonic plague occurred in Axim, and there was a recurrence in this part in July, 1918. In July, 1919, one death was recorded in Accra.

Sir William further points out that in view of the position of the Gold Coast and its trade relations with countries infected with plague, its comparative freedom from plague may be considered fortunate. He considers that some of the immunity of the Gold Coast during these years may be attributable to not possessing any port which admits vessels which may contain infected rats alongside its docks.

A table is given showing the plague prevalence and deaths in 1922 and 1923 in countries on or near the West Coast. Much other interesting information is also contained in this very complete and very well-written report. It also contains many excellent photographs which vividly convey the sanitary and general conditions of life on the Gold Coast.

Original Communication.

EPIDEMIOLOGICAL STUDY OF LEISHMANIASIS VISCERALIS IN SPAIN.

Report by Professor G. PITTALUGA,
University of Madrid.

(1) SINCE the year 1925 many hundreds of cases of infantile kala-azar or leishmaniasis visceralis have been observed and partly described. Further on [1] we give a bibliography of these cases, which, however, does not claim to be complete.

From my personal experience and data collected by my collaborators and pupils, one is bound to conclude that there exists in Spain (one may even affirm in the whole of the Iberian peninsula, as we shall see) a genuine endemic of leishmaniasis visceralis. This endemic is far from being localized or limited to the coast or the country near the shores of the Mediterranean. We know of more than a hundred local cases which occurred in the central and western provinces of Spain (Madrid, Toledo, Caceres, &c.). The epidemiological circumstances and ætiological agents of this disease make it, therefore, worth while to study it carefully in these surroundings.

Although cases amongst children of tender age predominate (from a few months to 10 and 15 years), we know of several cases of visceral leishmaniasis amongst youths and adults (15, 23 and 46 years). We prefer, therefore, and shall henceforth use on this account the term " Visceral Leishmaniasis " instead of the common designation of " Infantile Kala-azar."

(2) HISTORY.

The first cases of infantile leishmaniasis were observed and determined (through microbiological diagnosis by puncture of the spleen) in the neighbourhood of Tortosa (province of Tarragona) by my assistants Vilá and Torrademè in September, 1912. I went over this part of the country personally—it is highly infested by malaria—in the month of August of the same year. It is interesting, in my opinion, not only with regard to history, but on account of the demographical and epidemiological consequences which may be derived from them, to publish the means I used in order to induce the medical men of Tortosa and surrounding villages to share my absolute conviction as to the existence of leishmaniasis amongst the children of that locality. I had asked Dr. Torrademè, physician, of the village of Perelló (4,160 inhabitants, 20 kilometres from Tortosa) to make a retrospective investigation on statements made as to the causes of death amongst children in the civil registry of the town clerk's office of the village. I did not expect to find diagnoses of kala-azar; but, as the whole region is extraordinarily malarial and children suffering from malaria and enlarged spleen abound, one would expect that, in discovering in these records of mortality (causes of death) amongst children, some medical statements diverging from paludism and reminding one of the syndrome of leishmaniasis—for instance, " splenic anæmia "—we would be in possession of a serious argument in favour of leishmaniasis, that is to say, of an infectious and endemic disease, which could be clinically separated from malaria in a surrounding of endemic malaria notwithstanding the difficulties of a differential diagnosis. This reasoning was confirmed by the suspicions of the local doctors, in particular of Drs. Vilá and Torrademè, who for some time had been observing ailing children who did not react to quinine and whose characteristics of anæmia and splenomegaly did not entirely correspond to those of children infected with malaria.

The following are the results of the investigation [4] from January 1, 1904, to July 1, 1912: Different medical men who followed each other in Perelló had established, without any microscopic confirmation, for 42 cases of death (of which the majority were of children of less than two years; five between two and three years; one at the age of six) the following diagnoses:—

	Cases
Splenic leukemia	31
Splenitis or chronic splenitis	4
Hodgkin's disease...	4
Splenic anæmia	2
Pseudo-leukemic anæmia	1
Total	42

The same method of investigation had also been followed, almost at the same time (1913), by Vilá in Tortosa and by Martinez in Granada [5]. The two authors have published the records of children's mortality in several villages (Ametlla, Roquetas, Motril, Torvizcón, Sorvilan, Almuñecar, Darrical, Almegijar, Busquistar, Pitres, Beninar, &c.) during periods dating back to 10 and 15 years.

Both ascertained the same interesting fact, namely: everywhere, the physicians declared—the proportion being more or less high—cases of death in children, unmistakably due, by a deduction, a posteriori, to kala-azar infantilis.

This was more than a hint. Later researches have proved the accuracy of this reasoning. Torrademè—who at present (1925) directs the anti-malaria dispensary of Amposta-Aldea (Tortosa)—has recorded from 1914 to this date 52 cases of leishmaniasis, 17 of which were positive, as shown by microscopical examination after puncture of the spleen. Some of these cases were submitted, September 6 last, to the members of the Commission on Paludism of the Committee of Hygiene (Health) during their voyage of study in Spain. If we take in the village of Perelló the total number of supposed cases (1904-1912) and the number of those proved beyond doubt (1914-1925), we get an average of 5 cases a year for approximately 4,200 inhabitants. These 5 cases were children and their mortality has been 100 per cent. up to 1912.

Drs. Vilá and Torrademè also established (1913) the existence—in a small proportion—of spontaneous leishmaniasis in dogs in connection with this focus of visceral leishmaniasis among children. The study of the parasite (cultures, experimental inoculations, &c.) had been undertaken by us in 1913 in collaboration with Drs. García del Diestro, Vilá and others [6]. From

that date the observations have been multiplied successively in the provinces of Granada, Valencia, Barcelona, Tarragona, Castellon de la Plana, Alméria, Malaga, Murcia [7]. The puncture of the spleen, chiefly after the method of Caronia (prick without aspiration), has been generalized as a diagnostic method, according to the teaching of my school. At present it is practised by a considerable number of doctors in the villages.

In 1914 García del Diestro described the first case of infantile leishmaniasis in Madrid. At present we know of some 20 cases [8]. It is only during these later years that in the central and western provinces of Spain considerable centres of visceral leishmaniasis, chiefly infantile, have been detected, of which the most interesting is the focus of Talavera de la Reina (province of Toledo), where the director of the local anti-paludean dispensary, Dr. David Ortega, in collaboration with de Buen, Luengo and others, has succeeded in registering during two years 55 cases (all positive, as shown by the examination of the spleen).

In Portugal the first case of leishmaniasis was described by Diomisio Alvarez in 1910. It concerned a child, 9 years old, which had been splenectomized by the surgeon, Salazar da Sousa [10], apparently for tuberculosis of the spleen. Later on, up to the end of the year 1923 (I do not know exactly the posterior data), about 50 cases have been described, of which 45 per cent. concern males and 55 per cent. females; nearly all the cases, with the exception of one, an adult, studied in 1921 by Dr. Caeiro Carrasco [11], occurred in young children.

The most important centres of leishmaniasis in Portugal are situated in the low valley of the Tagus, on the outskirts of Lisbon, Monte Estoril, Santarem, Setubal, Silva. Cutaneous and mucous leishmaniasis (bouton d'Orient, American leishmaniasis) have often been observed in Portugal. Nearly all these cases had been imported from Brazil [12].

(3) General Statistical Data.

The cases of visceral leishmaniasis which have been traced or determined by diagnosis during the last few years are, of course, much more numerous than those traced in former years. General statistics of observations published since 1912 do not, therefore, give a true impression, proportional to the importance of the endemicity.

The figures are as follows [13]:—

(*a*) Cases of visceral leishmaniasis diagnosed by puncture of the spleen (presence of parasites):—

Province of	Barcelona	7
,,	Tarragona	53
,,	Castellon	78
,,	Valencia	58
,,	Alicante	8
,,	Murcia	3
,,	Almeria	9
,,	Malaga	1
,,	Granada	34
,,	Cordoba	4
,,	Madrid	21
,,	Toledo	55
,,	Caceres	11
,,	Badajoz	1
	Total	343

(*b*) Cases of infantile leishmaniasis where the diagnosis was based on clinical data (characteristic of splenomegaly), hæmatological[1] or therapeutical data (efficacy of treatment by stibiated[2] preparations) [14].

Observations of Dr. Torrademèl (Tortosa) ...	35
,, Dr. Comin (Valencia)	235
Various observations	50
	320

We shall, of course, retain as a basis for our later epidemiological study the figures of those cases only where the diagnosis was founded on microbiological evidence (343 cases have come to our knowledge). But we have added the figures of the cases where the diagnosis was established by clinical methods, because in Spain practitioners of great merit and undeniable experience hold that it is nearly always possible to furnish this diagnosis. We shall later discuss on this opinion to which I do not ally myself for scientific and pedagogical reasons.

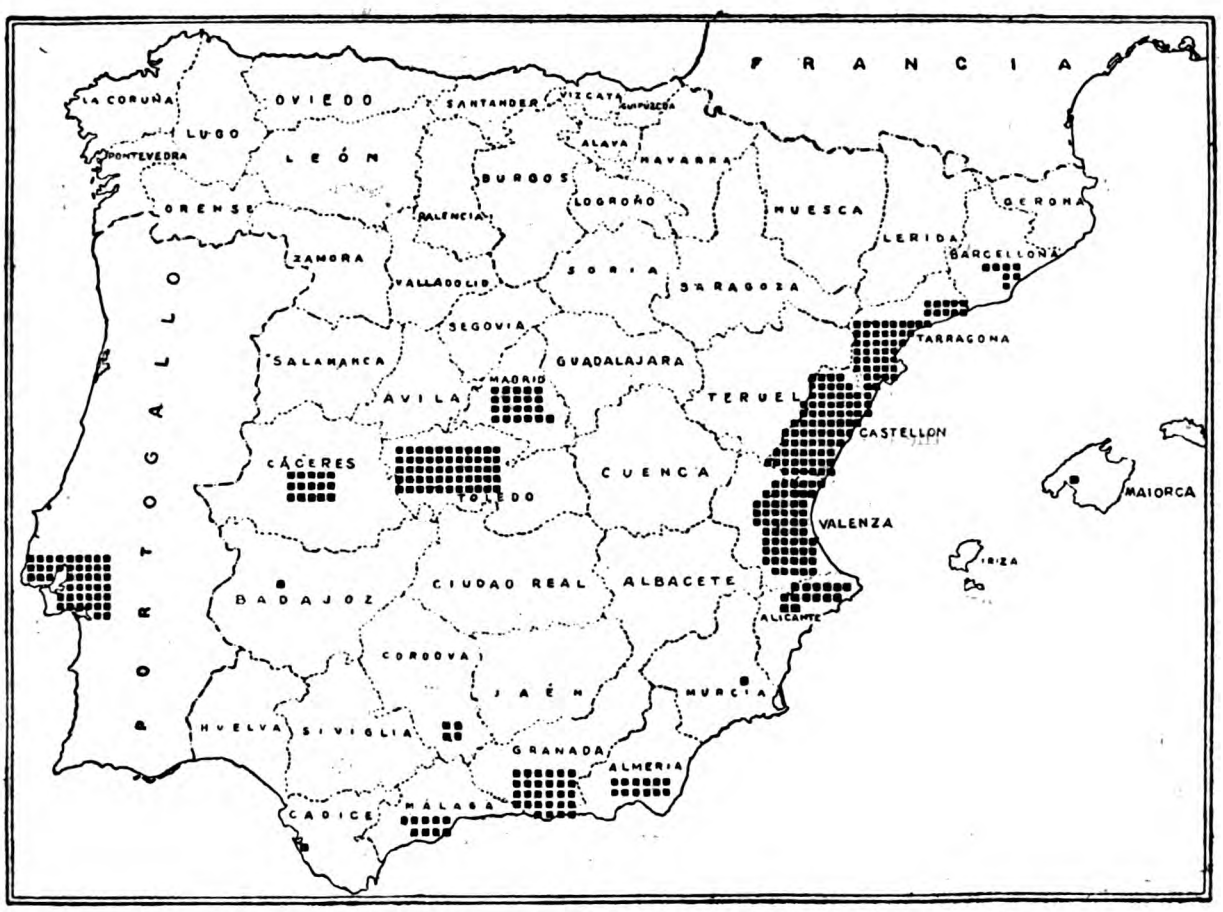
(4) Age and Sex of the Patient.

As regards age one may draw up the following table:—

Cases of leishmaniasis under 6 months		11
,, ,,	1 year	36
,, ,,	2 years	120
,, ,,	3 ,, ...	58
,, ,,	4 ,, ...	48
,, ,,	5 ,, ...	35
,, ,,	6 ,, ...	16
,, ,,	between 7 and 10 years	3
,, ,,	between 10 and 12 years	1
,, ,,	between 12 and 15 years	2
,, ,	at 23 years	1
,, ,,	at 46 years	1
,, ,,	at unknown age ...	11
	Total ...	343

The part sex plays is of much less importance. The cases may be divided as follows: 43 per cent. males, 57 per cent. females [15].

(5) Geographical Distribution.



By examining the above data (§3) the following conclusions may be drawn, *grosso modo*: (*a*) important hotbeds of visceral leishmaniasis exist along the oriental shores of the Mediterranean, with two predominating centres in Tortosa and Valencia; (*b*) those of the provinces of Alicante, Almeria, Murcia, Malaga seem to be smaller; (*c*) important foci exist on the western shores of the Mediterranean and in Andalusia (Granada, Cordoba); (*d*) finally, extremely interesting are the centres of infection existing in the western and central parts of Spain, where about one hundred cases have been registered, mostly in the province of Toledo (Talavera de la Reina), and even in Madrid, in Caceres, &c. (See map, page 389.)

Neither a site nor a single case has as yet been reported above 42° of northern latitude. The centres situated highest to the north are those of Barcelona and Reus, situated near 41° parallel.

[1] Leucopenia. [2] Antimonial.

As to altitude, it must be stated that most of the localities where the cases observed originated are situated in the plain, near the coast or at a height of not more than a hundred metres above sea level, with the exception of the villages in the Sierra de Gredos (Villanueva de la Vera, &c.), in the province of Caceres, observed by Dr. de Buen (1922), afterwards by Drs. Luengo, David Ortega and others (1923). These villages are situated at a height of about 300-450 metres above sea level. Certain villages of the southern part of the province of Valencia, as Onteniente, and the localities bordering the province of Alicante, as Cocentaina, where Naravra Huesca, even Castilla la Veija and Aragón), remain for the present unaffected by the disease, in spite of all reserves I have to make on the subject.

It must not be forgotten that the detection of the cases of leishmaniasis is part and function of medical culture and of appropriate professional training. We do not allude here to the northern province just mentioned, where the effect of the epidemiological agents of leishmaniasis is probably neutralized by the climate. It is, however, a fact that the centres of disease which up to the present have been traced were discovered where a good school of pædiatrists

Distribution of cases of leishmaniasis visceralis (infantile kala-azar) in Spain (1925).

Dr. Comin, children's specialist in Valencia, discovered cases of leishmaniasis, are also placed at heights varying between 250 and 400 metres. It must be kept in mind that we know of 20 local cases in Madrid in children born and bred in the capital or its suburbs (Ciudad lineal), viz., at an altitude of more than 650 metres.

It is true that a certain distribution as to climate, in connection with altitude and latitude, can be noted as regards the geographical distribution of visceral leishmaniasis in Spain. Thus the northern provinces (the whole of Galicia, Asturias, the provinces of Bilbao, Santander, San Sebastian, Vittoria, had striven to acquire the necessary knowledge as to local infantile epidemiology, or in the villages, where young physicians had exercised their art, inspired by our school of parasitology, or in those parts of the country where our organization for fighting paludism had sent its technical staff. This means, in my opinion, that, should one search elsewhere, one would, under similar climatic conditions, discover new cases; the distances which at present separate the important known centres of the disease would disappear or would be greatly reduced and the present aspect of the geographical distribution of visceral leishmaniasis, with its fragmentation and

localization without sufficient reasons, would be considerably altered.

(6) The Hotbeds of Leishmaniasis.

Which are indeed the characteristics of the existing centres of leishmaniasis? What is peculiar to them and what do they have in common? In what way do they differ from the neighbouring localities, where no cases of this disease have been encountered?

In order to answer these questions we shall have to examine more closely the conditions of living of the population, chiefly of the families who live in the midst of the hotbeds of leishmaniasis.

The result of this examination will show that the conception of the great centres of leishmaniasis such as they appear when examining the present geographical distribution of the disease, does not hold out against scrutiny. Evidently there exist centres of visceral leishmaniasis. Leishmaniasis is perhaps essentially a disease of small, localized centres, even limited to the home alone, as some observers (for instance, among the Italian school, Jemma and his collaborators, and in Spain, Camacho Alejandre, Torrademè, de Buen) [16] have maintained. But these small centres (small towns, suburbs, farms, &c., or villages separated from other villages, safe from disease) have precisely nothing in common with the great centres which now appear on the map (the focus of Talavera de la Reina, in the province of Toledo, or the centre of Tortosa or Valencia). To sum up, I consider the last named two as artificial centres. They exist owing chiefly to the activity of a circle of professional culture which stirred a current of investigation around them resulting in the detection of the sick. These large centres have probably nothing or very little to do with the real topography of the cases of leishmaniasis, neither houses nor localities infested with it; such a topography ought first to be established before speaking of hotbeds of the endemics, in the real meaning of the word.

(7) Social Conditions.

The sick children belong in a great majority to poor families. But many cases apply to better people, or even to middle-class families in excellent economical conditions. The case of a girl, 11 years old, who lived in a villa in Ciudad lineal (suburb of Madrid) and belonged to a middle-class family—her diagnosis was established in May, 1924 (puncture of the spleen) by Dr. de Buen; a case studied and treated by myself and my assistant, Miss Gonzalez Barrio (1921); a case observed by Dr. David Ortega in Talavera; the case of a child, a cavalry officer's son, sent to me for consultation by Dr. Camacho Alejandre (1923), and other cases prove that social conditions, as far as they depend on a good economic situation of the family, do not exclude infection. But the hygienic conditions of life, chiefly those of rural or semi-rural dwellings (with a garden, poultry yards, cattle, &c., water-closets in bad condition, or non-existing, &c.) are of a primary importance. Even in the cases just mentioned, which concerned well-to-do families, such defects are to be found. The small site of infection of Ciudad lineal, near Madrid (where several cases originated), is characteristic in this respect; it is a closed-in district, formed by small houses or villas, with their own garden, a poultry yard, &c. Other local cases in Madrid originate in other populous districts, situated on the outskirts of the town, where the type of dwelling is already rural.

With regard to some of the patients living in town (in one case, a house in the centre of Madrid), we are certain that infection was contracted in the country (province of Almeria) [17].

(8) Canine Leishmaniasis and Domestic Centres of Visceral Leishmaniasis (Houses of Kala-azar).

The coincidence of certain centres of spontaneous leishmaniasis in dogs, with cases of visceral leishmaniasis in man, has been ascertained in Spain since 1913. Vilá and Torrademè have found infected dogs in the neighbourhood of Tortosa in a proportion of 4 positive cases for 65 dogs examined (6 per cent.) [18]. Camacho Alejandre discovered a still higher proportion (22 per cent.) for 7 dogs in direct contact with sick people (dogs belonging to houses of kala-azar). I have endeavoured myself, with Dr. García del Diestro, and later with Miss Gonzalez Barrio and Mr. Campuzano, Professor of the Veterinary School in Madrid since 1914, to trace dogs with leishmania in connection with the cases of leishmaniasis on the outskirts of the town of Madrid, without any positive result, however. Campuzano has examined some 15 dogs, more or less in contact with human cases, and over 200 dogs taken at random in Madrid and in the suburbs, all with negative results (spleen and liver). The veterinary inspector of Valencia, Trigo Mezquita, published in 1916 the result of an examination of 313 dogs, with 3 positive cases. Lately, de Buen took up these researches in the zone of Caceres, but without any positive result.

It must be admitted, nevertheless, that a methodical investigation on dogs, pursued in localities infested by human leishmaniasis, especially kala-azar-infected houses, has not been attempted and is urgently needed in a country like Spain, where the dog is constantly and intimately associated in rural surroundings with domestic life. Some observers—for instance, Camacho Alejandre (Almuñecar, Granada)—insist on the importance of this cohabitation and the consequent formation of small foci of human and canine leishmaniasis, both occasionally appearing isolated, viz., separated from each other in the same locality.

(9) The Parasite.

The parasite, pathogenic agent of visceral leishmaniasis, observed in human beings in Spain, does not differ from the type *Leishmaniasis infantum*. Its morphological and biological characteristics in the organs of the sick child (spleen, liver, bone-marrow), in cultures and experimental inocula-

tions (dogs), have been described since 1913 by us and our collaborators, García del Diestro, Vilá, Gonzalez Barrio, &c., by Fernandez Martinez, of Granada, by observers of the School of Barcelona (Sayé and Alomar, Pi Suñer, Carrasco, Roiy, Martinez Vargas and others), by Gomez Ferrer, Aguilar Jordan, Comin, and Peset in Valencia, by de Buen [20]. We refer the reader to these works and to the summary of the subject in my book, "Diseases in Hot Countries and General Parasitology" (1923).

The leishmania of dogs, whether spontaneously infected or experimentally inoculated with human virus, nearly always affect a slightly elongated form, pear- or egg-shaped, with a longitudinal diameter of two microns, or more, and a transverse diameter not exceeding 2 microns. One very seldom finds in the smears from dogs the round shapes with large nuclei (trophonucleus) and with rounded punctiform blepharoplast, which are met, chiefly when infection is recent, in the organs of children—in particular in the perithelial cells of the hæmohistiocytarian type (hæmohistiocytes and hæmohistioblasts of Ferrata) [21]. But the fact that this morphological character (besides being of small importance, as the pear-shaped forms are equally met with in infantile leishmaniasis) appears both in the leishmania of spontaneous infection of dogs, as in the parasites of human stock experimentally inoculated into dogs—seems to prove that their species does not differ, as least as far as their structure and morphology are concerned.

The leptomonas (flagellated forms) in cultures (on blood-agar N.N.N.) are identical.

In the parasitized organisms we have met leishmania also in peripheral blood, chiefly in the leucocytes (monocytes and neutrophilic granulocytes) [22]. These parasites are nearly always round with slightly elongated corpuscular blepharoplast. I consider these shapes as an indication of recent infection. Even when met with in the endothelial or perithelial cells, or in general in the reticulo-endothelial system of the organs, they are probably in relation with the hæmatic phase of the parasite, which seems to be demonstrated, too, by their much more reduced number in the interior of the cytoplasm of the elements where they lodge, as compared with the number of parasites of the pear-shaped type, or, in general, of the type with elongated stick-shaped blepharoplast. If I insist on these observations it is because they are related to the problem of the parasite's introduction into the organism of men and mammals and, more strictly, to the structure and morphology of the parasite in the initial periods of its development, after inoculation. This question is directly connected with the aspect of the parasites at the time of inoculation, in the insect or insects which may be incriminated as the intermediary hosts, or as the carriers of the virus of leishmaniasis.

(10) Transmission of Visceral Leishmaniasis. Carrier Insects and Receptacles of Virus.

Our present knowledge as to the transmission of visceral leishmaniasis results from the critical examination of the following hypotheses:—

(*a*) Direct or indirect transmission of the virus from the intestinal mucous membrane, chiefly by intestinal worms.

(*b*) Transmission by fleas of men and dogs.

(*c*) Transmission by bugs.

(d) Transmission by hæmatophagous nematocera (Culicidæ) or brachycerous diptera (Tabanidæ).

(*e*) Transmission by phlebotomes.

We shall here deal summarily with the data concerning these different hypotheses resulting from personal experience and that of Spanish investigators.

(*a*) The direct transmission of the virus by the intestinal canal—a theory which, formerly defended by Donovan, and more recently, concerning Indian kala-azar, by Mackie, by Archibald and others—cannot be admitted in most of the cases of leishmaniasis infantum, and this, in our opinion, for the following reasons:—(1) In cases concerning children of tender age, for instance, 3 months, fed exclusively at the breast of the mother, it is difficult to imagine an infection by resistant forms of leishmania, which ought to proceed from the bowels of a sick person, or from a carrier of virus, which should have contaminated the water or an object having come in contact with the infant's mouth. (2) The forms of leishmania known to us, outside the organic internal medium, namely, the leptomonas forms of cultures, are extraordinarily sensitive to all contamination of the soil by bacteria in general, as we have ascertained with all the species (human and canine) inoculated by us; accordingly, it is difficult to assume that they are apt to multiply or to remain in the intestinal canal, preserve their vitality, and finally be evacuated. It is, moreover, a hypothesis which, for many other reasons, does not withstand further criticism. The indirect transmission by inoculation through the intestinal helminths—which, by the way, has been discarded lately in India by the researches of the commission presided over by Christophers [23]—is contradicted in Spain by the following facts: (*i*) There are no nematode parasites (the only helminths which could be incriminated as inoculators) to be found in the intestines of infants of low age, viz., at an age when leishmaniasis is most frequent. (*ii*) A very high proportion of elder children in our rural districts (between 3 and 15 years), and adults who harbour intestinal helminths (Oxyuris, Ascaris, Trichocephalus) do not show any symptoms of leishmaniasis. (3) Negative result as to the presence of helminths' eggs in excrements examined of several children suffering from leishmaniasis. (4) No eosinophilia in nearly all the cases of leishmaniasis observed in Spain and whose leucocytarian formula has been established (some hundred cases) [24]. (5) No coincidence between the larger foci of ankylostomiasis [25] and part of the actual foci of leishmaniasis (Madrid, Talavera de la Reina, &c.).

(*b*) Transmission by Fleas.—The hypothesis sustained by Nicolle (1908) and defended later with such tenacity by Basile—is still the one which seems to rally, in Spain, the greatest number of adherents. Since 1913 Vilá and Torrademè have endeavoured to study the habits of the fleas of dogs (*Ctenocephalus canis* and *Pulex serraticeps*) in

their connection with children; Vilá even examined the fleas of infected dogs. We have made during the years 1913-1914, in the Institute of Hygiene Alfonso XIII, a series of observations on fleas of dogs, experimentally inoculated with the virus of the infantile leishmania of Tortosa. The objection, resulting from Wenyon's works on the herpetomonas of fleas, remains still the most serious difficulty for resolving the question of an evolutionary phase of the leishmania in the intestines of fleas. From the protistological point of view the problem is not modified. Nevertheless, there are reasons of an epidemiological order, in our opinion, which neither plead in favour of the hypothesis, the dog as a receptacle of virus—nor of the other—the transmission of the virus by the fleas of either dogs (*Ctenocephalus canis*) or men (*Pulex irritans*). This does not affect the problem of identity between the viruses of human visceral leishmaniasis (kala-azar infantum) and leishmaniasis canis, nor does it concern the possibility of an experimental inoculation. The confusion created between these two problems has been prejudicial to their solution. It is quite possible, and I am of the opinion that the parasite is the same; but it is very likely, too, that the intermediary host or transmitting agent of leishmaniasis is not an ectoparasite, as strictly and constantly associated to the life of the dog, as the *Ctenocephalus canis*. Indeed, should that be the case, how would one explain the great difference which exists in Europe and in Northern Africa between leishmaniasis of dogs taken at random and leishmaniasis of dogs proceeding from endemic foci or houses of kala-azar infantum? I need not recall here the observations of Coronia and Di Giorgio, who discovered in Palermo only a single positive case for 1,005 dogs, picked up in the streets and examined by them. Jemma also obtained, a few years ago, a negative result for 300 dogs examined, from the same place. Now the same author found two infected dogs out of seven examined in the suburbs of Palermo, which are foci of leishmaniasis infantum. The high percentage observed by Basile near Messina (in Bordonaro)—the highest known (81 per cent. for dogs examined)—is in relation to one of the most important hotbeds at present known (Gabbi, 1909). I shall not reproduce here other existing statistical data on canine leishmaniasis in Italy, Greece, Russia, Tunis, Algeria, Morocco, Dekar, &c. I only wish to emphasize one fact, i.e., in Spain all the data collected, up to now, lead to the conclusion that spontaneous leishmaniasis of dogs taken at random (street dogs, dogs in the country) seldom occurs, while the proportion grows if one takes dogs which are in contact with human cases of kala-azar. An observer as careful as Dr. M. Vilá (of Tortosa) did not find a single animal infested with parasites in 43 dogs examined (spleen, liver, bone-marrow). Later a dog from the village of Aldea and another from Camartes, foci of leishmaniasis infantum (Torrademè and Vilá, 1913), gave positive results. We have already mentioned elsewhere (§8) the data furnished by Messrs. Torrademè, Camacho Alejandre, Campuzano, Trigo Mezquita, de Buen. From the total of these researches the following figures can be deduced:—

	Number of dogs examined	Number of positive cases	Proportion per cent.
(1) Dogs taken at random ...	558	3	0·54
(2) Dogs from houses with leishmaniasis	52	6	11

It must therefore be admitted on the one hand that in those localities where human cases of visceral leishmaniasis occur and where, on the other hand, the proportion of infected dogs is high, there intervenes a factor which must not be exclusively and intimately associated with the life of men and dogs, but which, moreover, is in connection with some local circumstances. This deduction can still be supported by other facts: there certainly are cases where it is extremely difficult to establish a relation between the existence of human cases and the presence of the dog. With my former assistant, Miss Gonzalez Barrio, we have seen a young patient, the daughter of a railway official, who had never left Madrid and did not possess a dog. In Naples for 110 observed cases (clinic of Professor Jemma) Javarone affirms to have succeeded only ten times in establishing the presence of dogs in the home of the sick person. I should like to recall the case reported by Jemma [26] of a little girl 17 months old, living in a suburb of Palermo, in the house of wealthy parents who observed the precepts of hygiene. More than two years before, that is to say, previous to the birth of the patient, an elder brother died of leishmaniasis. At that time a dog was kept in the house; that dog had been examined by Professor Jemma. It carried no leishmania. Notwithstanding this the father, alarmed by the doctor's opinion, did not want to continue keeping his dog. The animal was therefore no longer in the house when the girl was born, and all precautions were taken by the family to avoid the least contact between the baby girl and dogs. The girl, nevertheless, contracted kala-azar. One may also quote the following observation: Contrary to the fact that the proportion of infected dogs in certain centres of human leishmaniasis is higher than among dogs taken at random, one finds certain centres (houses, small towns) of infantile kala-azar where dogs do not carry the virus.

We arrive then at the following conclusions: (1) The dog does not seem to constitute a receptacle of virus—independent of the foci—of human leishmaniasis. (2) The parasite does not appear to be transmitted by an insect, as intimately associated with the life of the dog as the *Ctenocephalus*, because in such a case one would probably observe a much higher proportion of disease among dogs in general. (3) The infection of the child is not always related to the presence of dogs. (4) The child and the dog probably get infected in certain places where there exists, under favourable circumstances, a common factor of infection, probably an intermediary host not as intimately connected with the life of the dogs as are the fleas, but who could infect (by stings or other means) the child and the dog as well. The in-

fection of the house cats, under these circumstances, is also possible. Vilá (of Tortosa) found a sick cat (sent to us in 1914); so did Sergent, Lombard, Gurlichini and others. These conclusions could be admitted, should one incriminate chiefly the *Pulex irritans* (common fleas of men) and not the fleas of dogs (*Ctenocephalus canis*). Now, the ubiquity of these ectoparasites is far from being equal in the two hosts.

In Spain, Italy and generally in Mediterranean and subtropical countries, fleas of dogs are found frequently on men. On the contrary, fleas of men are found in dogs under much more accidental circumstances. One ought to admit, therefore: (*a*) either that canine leishmaniasis is due to a different virus, transmitted by the *Ctenocephalus* to dogs alone: (*b*) or that the *Pulex irritans* is the only real transmitting agent of the leishmania.

One may invoke against the first hypothesis: the scarceness of leishmaniasis among dogs taken at random; the high proportion of the disease in centres of kala-azar infantum; the morphological identity; the experiments of Nicolle, Basile, &c. (inoculation of the human virus into dogs); those of Novi, performed with cultures; the results attained with the two kinds of fleas by Basile, &c. Against the second hypothesis I plead the conclusions arrived at by such authors who succeeded in transmitting the human virus experimentally to dogs, chiefly through the *Ctenocephalus*, as much as the relations existing between the fleas of men and dogs, &c. I think, nevertheless, that this question ought to be taken up again, without canine leishmaniasis being allowed to trouble our mind overmuch. The observations of La Cava, Visentini, Basile, &c., on *Pulex irritans* (fleas of men) infected on dogs are decidedly suggestive. We have to start from the conception that the dog is not the receptacle of the virus for men. As for kala-azar in India, the non-existence of spontaneously infected dogs (or their scarceness) has done much to free the mind of the epidemiologists from some preconceived ideas. On the whole we cannot reject the hypothesis of the fleas; we submitted it to critical analysis; we think that it ought to be taken up again by an experimental and parasitological study, which should not be overruled by Nicolle's categorical affirmation that infantile kala-azar is a natural infection of the dog transmittable to the child [27]; this affirmation, which has opened the path to most important investigations and has given so many fruitful results, does not seem any longer to agree with the actual state of our knowledge.

(*c*) Transmission by bugs.—The hypothesis sustained by Patton and others as to kala-azar in India appears in Spain to be contradicted by the following facts: (1) The very filthy urban centres where bugs abound, as it happens in some houses with a very considerable number of tenants (" casas de vecindad " in the suburbs of Madrid, with five hundred, even a thousand, people living in the same block, comprising from one hundred to two hundred small bedrooms), have not, up to the present, contributed any cases of kala-azar. (A serious investigation as to this matter remains to be undertaken). (2) Some houses of kala-azar, in villages even, are very clean and have no bugs. (3) In some houses healthy children generally live and sleep with one or several of their younger brothers and sisters, ill with leishmaniasis, or even with sick adults; now, the habits of bugs, their voracity, &c., are such that it is difficult to conceive, under these circumstances, an inoculation limited to certain individuals only. It is well to recall here that some of the foci of leishmaniasis coincide, for instance in the Province of Caceres, with cases of recurrent fever with " spirochæte recurrentis " which have been traced during these last years by Mr. de Buen and others. They concern spirochætosis transmitted by bugs; and we know that the *Cimex lectularius* can be the transmitting agent. In any case this assertion gives one an indication as to the abundance of the domestic ectoparasites.

(*d*) The part played by the hæmatophagous diptera, belonging to the species of Culicidæ, Tabanidæ and Muscidæ, must, in our opinion, be taken but little into account, save, perhaps, as regards the transmission of cutaneous leishmaniasis, for which Cardomatis has incriminated flies.

(*e*) Transmission by the Phlebotomes.—The hypothesis advanced in 1914 by Sergent, Lemaire and Senevet, concerning the transmission of cutaneous leishmaniasis by the phlebotomes and the possibility of a receptacle of virus (cold-blooded vertebrate) has induced us, in collaboration with de Buen, to study the Spanish phlebotomes [28]. Since 1916, thanks chiefly to Mr. de Buen's personal researches, we know to a certain extent the geographical distribution and localization of four species of phlebotomes in Spain:—

Phlebotomus papatasii (Madrid, Escorial, Navalmoral de la Mata, Talavera de la Reina and surroundings, Granada, Malaga, Tortosa, Palma de Mallorca, and other places);

Phlebotomus legeri (*perniciosus*) (Malaga, Palma de Mallorca, Granada, Araujuez, Huelva);

Phlebotomus minutus (Navalmoral de la Mata and surroundings, Province of Caceres; Granada, Malaga, Palma de Mallorca);

Phlebotomus sergenti (Navalmoral de la Mata Granada).

The biology and habits of these small diptera, better known since the excellent works of Grassi, Newstead, Summers and Larousse, are most interesting from our point of view, as they coincide with several epidemiological characters of leishmaniasis in general and of visceral leishmaniasis in particular.

The demonstration given by Parrot, Sergent, Donatien and Béguet as to the possibility of inoculating the leishmania of oriental sore into the skin of men through scarification with infected phlebotomes (1921) has still further increased the interest of these investigations. Recently (1924), in the works of Knowles, Smith and Napier, undertaken in India under the direction of Christophers, the phlebotomes are considered as the transmitting

agents of *Leishmania donovani*, of Indian kala-azar. The experimental results gained so far are highly instructive, and they compel one to examine seriously the same possibility with regard to European visceral leishmaniasis.

The phlebotomes abound in Spain all through the summer in rural or semi-rural houses of certain localities. They are even met with in towns (Madrid, Barcelona), but in garden districts only, where certain conditions peculiar to country surroundings (as old walls, poultry yards, &c.) prevail. They are sometimes very numerous in bedrooms, but they are generally found hiding in dark places, in small untenanted rooms, &c. At all events they concentrate in certain farms, houses, cottages, huts and hovels, which they appear but seldom to leave. One meets with sporadic foci of phlebotomes; they are plentiful in some places, and close by in the same locality there are often none to be found. This fact is most striking for its coincidence with the distribution of kala-azar.

In connection with the phlebotomes it is necessary to examine the reptiles on which they feed for preference.

In Spain, in localities where phlebotomes are found, the small saurians commonly called tarante or geco (*Platydactylus mauritanicus*) are very frequent. According to Sergent, Lemaire and Senevet, these small saurians constitute a receptacle for the virus of cutaneous leishmaniasis. S. de Buen has ascertained the presence of these reptiles in almost all the localities where the phlebotomes dwell and where visceral leishmaniasis has also been observed. Yet he has not succeeded in tracing platydactyli, carriers of parasites, comparable to the leishmania. My resident pupil, Mr. Elosegui, has examined during these last months the blood and organs of fifteen platydactyli in Olivenza (Badajos) with negative results. These investigations, so far bearing only a tentative character, ought to be continued with method and to operate on a more copious material for study. I have examined personally a hundred phlebotomes (*P. papatasii* and *minutus*) caught in Talavera de la Reina in houses where cases of visceral leishmaniasis had occurred, by Mr. Gil Collado, entomologist of the Malaria Commission, and Mr. David Ortega. I found not anything, either in the intestinal contents or between the coat cells of the alimentary canal, which might recall a known form of the evolution of leishmania.

My collaborators and myself had neither the time nor the means to pursue these observations systematically, or to attempt an experimental study.

We believe the following to be essential: (1) The breeding of phlebotomes in the laboratory; (2) to feed these phlebotomes on dogs, bearers of leishmania; (3) to transmit, through the stings of these phlebotomes, the infection to young healthy dogs; (4) to try the same experiment with human virus; (5) to feed the infected phlebotomes on platydactyli and sacrifice the latter successively at periods more or less remote from the time of inoculation; (6) to study, by histological and cytological methods, the possible evolution of the leishmania, whether of human or canine stock, in the alimentary canal of the organs of the invertebrate. It is a very arduous task which requires financial means which we, unfortunately, do not possess.

(11) Visceral Leishmaniasis and Cutaneous Leishmaniasis in Spain.

Observations on oriental sore have been published in Spain (Granada, Malaga, Almeria) since 1913 by Camacho and Fernandez Martinez (microbiological diagnosis. Numerous cases, clinically diagnosed, have been brought to our knowledge by physicians of the southern coast of the Mediterranean. We cannot furnish at present any data favourable or contrary to the hypothesis of immunity from visceral leishmaniasis brought about by cutaneous leishmaniasis.

(12) Clinical Syndrome and Evolution of Visceral Leishmaniasis in Spain.

Some ten years ago only very serious syndromes were observed here. Subsequently sick people were discovered, chiefly children, finding themselves, if not in the initial, at least in the slightly advanced stages of the disease. Those of our practitioners who work in localities infested with kala-azar easily diagnose leishmaniasis—and even this in districts with intense endemic malaria—by the paleness of the skin; by irregular fever with multiple remittances during the day; by the precocious and very accentuated splenomegaly; by the anatomical characters of the spleen, which distinguish it from the dilated spleen of malaria. For a long time we have insisted on the fact that there are many benign cases of kala-azar of very slow evolution, the little accentuated syndrome of which has to be traced and established by exclusion and the diagnosis of which ought to be confirmed by a microbiological examination of the spleen. I believe that the evolution of the disease in a great many cases which we ignore, or which we diagnose at a very advanced stage in children of 8, 10 and even 15 years (see § 4) or in adults, is much slower than we think. We probably only notice the cases with a malign or rapid evolution, or, on the whole, the grave ones. There is no doubt that when we get to establish a hereditary taint in the child, or an indirect and independent cause of less resistance, the leishmaniasis presents a more serious character and does not yield, or yields much less, to the action of compounds of antimony (stibio-resistance). We have had some striking cases, of which one (a child of 7) has been followed by all my collaborators for more than two years. This child, whose development was obviously arrested, was probably heredo-syphilitic. It had two or three successive relapses, and died, in spite of the most intense and careful treatment. Miss Gonzalez Barrio, in a remarkable case of stibio-resistance, which I had diagnosed four years years ago by puncture of the spleen, found the Wassermann reaction positive, not only in the child but also in the mother (who had had miscarriages).

(13) Diagnosis and Tracing of the Sick.

The fundamental basis for the study of the epidemiology of leishmaniasis is the tracing of the sick and the diagnosis of their illness. We have already clearly expressed our view concerning the artificial nature of the foci at present existing in great centres of leishmaniasis. They are all related to the existence of spheres of specialized medical science, or due to the presence of doctors particularly devoted to their task or to schools of parasitology or pediatry. We are absolutely convinced of the necessity to intensify the active influence of these elements and we think that by so doing a considerably greater number of cases of leishmaniasis will be detected: thus the true localization of the illness will be attained.

Our school has always insisted on the necessity of the parasitological diagnosis, and we have succeeded in introducing spleen puncture as an elective process, indispensable for the microscopical diagnosis, even into rural districts. In the large towns or suburbs the doctor in charge of the Municipal Services of Assistance are already accustomed to direct suspicious cases to our laboratories to have the puncture applied. I agree with Nicolle and Jemma in advising puncture of the spleen, and prefer the method for practical reasons and the positive result it furnishes to any other means of microscopical investigation of leishmaniasis.

A certain tendency has manifested itself recently with the pædiatrician and in certain rural districts towards giving a decisive importance to the clinical diagnosis and even denying the necessity of a microbiological confirmation of the diagnosis in the case of infantile kala-azar. Thus, for instance, Comin, assistant professor of pædiatrics in Valencia, a friend and old pupil of mine, states as proved cases of leishmaniasis during the last five years, 286 cases, observed by him in the province of Castellon, 43 in the province of Valencia, and eight in the province of Alicante. But, of the total of these 337 cases, only 102 were diagnosed microbiologically by spleen puncture, in collaboration with Professor Peset. It is true that Comin recommends, when resuming the conclusions of his work, the application of splenic puncture, though he thinks that an exact diagnosis can be established clinically.

The same opinion is upheld, even with more tenacity, by our friend and collaborator, Dr. Torrademè, who practises in Perello, near Tortosa. He believes the puncture of the spleen to be sometimes dangerous. Torrademè has carefully established all the differential characters between infantile kala-azar and children's malaria, and he maintains that the clinical diagnosis suffices.

We cannot accept that opinion. Even if we admit that the children affected by kala-azar have indeed a typical facies, even if we take into account the anatomical characters of the spleen of kala-azar which present nearly always a very pronounced notch on its antero-interior edge, as a consequence of the organ's precocious sclerosis, we, nevertheless, insist on the necessity of controlling the clinical diagnosis by the search for parasites. Spleen puncture is a trifling operation which in most cases causes no inconvenience. Finally, from the epidemiological point of view, it is possible to rely only on cases where the presence of the parasites has been proved.

The hæmatological and serological data are interesting (Brahmachari's and Napier's reaction, &c.), but the only alteration observed in a very high percentage of cases, and which really guides the clinical practitioner, is leucopenia.

(14) Efficacy of Treatment and Statistics of Mortality.

The treatment by antimony, in particular by the emetic (double tartrate of antimony and potassium or sodium), is very efficacious. In Spain the organic preparations of antimony have been much used (stybenil, Leyden 611, and Bayer 211 and 212, &c.). Comparisons between the results obtained by these different remedies have been established chiefly by David Ortega in Talavera de la Reina, who has observed and treated 55 cases of leishmaniasis during the last two years. The aggregate therapeutical results he obtained are the following: 33 patients may be considered as cured (60%); 14 patients died (24·5%); 9 patients are under treatment.

Torrademè, in Tortosa, believes he has obtained 7 cures on 11 cases treated with stybenil (= 63%).

Comin, in Valencia, has obtained less favourable results: 196 died out of 252 sick treated = 77%: 56 cured = 23%.

In my opinion such a difference is due rather to the therapeutical methods employed than to the system of moving dispensaries, which do not permit the observance of the sick with the assiduity and regularity demanded by the treatment, and above all, to the delayed diagnosis which had been established at a very advanced stage of the illness.

The observations of the Madrid pædiatrists, of de Buen, Luengo, Iglesias and others in the province of Caceres, and my personal investigations give figures approaching the result of Ortega in Talavera.

These therapeutical results, which Jemma and his collaborators (who attained the total of 85% cured) have surpassed, are very important from the prophylactic point of view. A parasitic illness of the type of an intermediate insect vector (which is very probably the case in kala-azar) requires always, as a means of contention, complete treatment of the virus bearer.

But it is particularly important to persuade the doctors not to undertake the specific treatment without the confirmation of the diagnosis by microbiological examination.

(15) The Probable State of the Present Endemic of Visceral Leishmaniasis in Spain.

The considerations just exposed concerning the reasons which provoked the appearance of what we

call " artificial hotbeds " of leishmania, at present known in Spain; their existence in provinces, even very distant from the coast; the progressive increase of the diagnosed cases in the course of these last years; the detection, almost daily, of sick people in the suburbs of large towns, like Madrid—lead us to the following conclusion: the cases of visceral leishmaniasis are much more frequent than they at present appear to be; we have to deal with a real endemic which has contributed in a large measure to infant mortality; a part, at least, of the forms of anæmia, pseudoleucæmia, splenomegaly, anæmia or atrepsia, which figure as causes of children's mortality must, indeed, be ascribed to leishmaniasis. The organization of a series of epidemiological inquiries and the application of preventive measures by the State and Sanitary Institutions, in general, impose themselves in Spain, as well as in the other Mediterranean countries.

(16) Plan of Work.

We think that, first of all, three inquiries have to be carried out.

(*a*) One of statistics, which should comprise a detailed revision of the declarations as to the causes of death in children in all the villages, towns and districts situated in climatological conditions similar to those of the localities where up to the present day cases of leishmaniasis have been ascertained;

(*b*) An inquest of the clinical and microbiological type directed by specialized practitioners. These should take as a basis for their investigations the different centres of research around which the present hotbeds of leishmaniasis have been recognized, and to them should be allotted the task of discovering new cases by means of spleen puncture;

(*c*) An entomological and parasitological research including the study of the children's ectoparasites, those of men in general, dogs, &c., the researches to be connected with one of the present existing centres of epidemiological studies.

These investigations would form the basis of experimental researches and should, in my opinion, be undertaken after a very thorough study of local factors and of the habits of domestic life of the people affected by leishmaniasis.

BIBLIOGRAPHICAL NOTES.

[1] This bibliography is collected in the work of P. Luengo, de Buen, and E. Luengo: " Siete casos de kala-azar infantil en las provincias de Cáceres y Toledo " (*Archivos de Cardiologia y Hematologia*, Octubre, 1922), and in my book: " Enfermedades de los paises cálidos y Parasitología general " (edit. Calpe, 1923). The new cases published last year by the members of the Commission for fighting paludism in the central provinces are described in the following publications:—

S. de Buen. " Un caso de kala-azar en la provincia de Cáceres," *Archivos de Cardiologia y Hematologia*, Junio, 1922.

P. Luengo, S. de Buen y E. Luengo. " Siete casos de kala-azar infantil " (Provincias de Cáceres y Toledo), *ibid.*, Octubre, 1922.

S. de Buen. " Algunas consideraciones sobre el kala-azar infantil en España," *Revista de Hig. y Tuberculosis*, Octubre, 1922.

Idem. " Apunte sobre la naturaleza de las células parasitiferas de los bazos leishmaniosicos," *Arch. de Card. y Hemat.*, Enero, 1923.

Iglesias. " Una endemia grave de leishmaniosis infantil en España," Memoria Doctoral, Abril, 1923.

[2] Messrs. García del Diestro, Gonzalez Barrio, Romeo Lozano, Bravo Frias, Fernandez Truegas are the Madrid pædiatrists who have occupied themselves chiefly with leishmaniasis. It is to M. Garcia del Diestro we owe the knowledge of the first local case of Madrid: " El primer caso de kala-azar en Madrid," *Revista clinica de Madrid*, Diciembre 30, 1914. The puncture of the little patient's spleen was practised in my service of the Institute of Hygiene Alfonso XIII, by M. Garcia del Diestro and myself.

The children's specialist, Mr. E. Suñer, at present Professor in Madrid, has studied lately a certain number of cases, four of which have been quite recently published by Miss Gonzalez Barrio: " Nuevos casos de kala-azar en Madrid y su provincia," *Archiv de Cardiologia y Hematologia*, Madrid, August, 1925.

Mr. Martinez Vargas (pædiatrist in Barcelona) and Messrs. Gomez Ferrer, Aguilar Jordan, Comin (of Valencia) have greatly contributed to increasing our knowledge concerning the endemic of leishmaniasis in Spain.

[4] G. Pittaluga—*loc. cit.*, Octubre 1, 1912—and J. Torrademè: " El kala-azar infantil en el termino municipal de Perello " (Tortosa). Doctoral Thesis, Madrid, November, 1914.

[5] Manuel Vilá. " Contribución el estudio del kala-azar infantil en el partido judicial de Tortosa." Doctoral Thesis, 1913, printed by Guerol, Tortosa (see p. 62). You find in Tortosa, for example, twenty-seven cases of children's deaths between 8 months and 5 years, declared as " leucemia," " splenitis," " anémia perniciosa," " noma," &c., between 1903 and 1912.

Fidel Fernandez Martinez gives in his doctoral dissertation (" El kala-azar en las costas granadinas," 1913, Granada, imp. Guevara), as well as in later publications, the totals observed in seventeen villages in the provinces of Granada and Almeria. Some of these figures are interesting as pointing to the endemic character of kala-azar (Motril, &c.).

[8] The two last-named cases, as yet unpublished, were directed for puncture of the spleen to my laboratory by my colleague and friend, Mr. Bravo Frias, Public Assistance doctor of the town of Madrid, and specialist in children's diseases. One of the cases has been observed by Professor Nocht and Professor Brumpt (August 17, 1925).

[9] Of these fifty-five cases more than thirty have been presented on August, 18, 1925, at the dispensary of Talavera de la Reina (Toledo), by Mr. David Ortega, to the Commission on Paludism, during its stay in Spain. Among these sick persons was a woman of 23 years.

[12] See the works of Padesca (*Arch. de Hig. e Patol. exot.*, Lisbôa, 1913), and those of F. E. Franco ("Two cases of cutaneous leishmaniosis," *A Medicina Contemp.*, Lisbôa, 1915, pag. 203; and "Contribuzione alla conoscenza dell' Anatomia patologica della leishmaniosi cutaneo-mucosa od americana," *Arch. por le scienze mediche*, Torino, 1922).

[13] The diagnosed cases increase daily. It is, therefore, difficult to fix their exact number at a given date. The topographical map accompanying this memoir will give a sufficiently clear idea as to the distribution of the cases and their number in Spain. On that map, which was drawn at the last moment, figure fifteen cases more than in the statistics examined in the text. They concern cases communicated quite recently.

[14] The specific characters of kala-azar splenomegaly have been accurately described in various publications of our school and demonstrated to the members of the Commission for fighting paludism in Talavera (August 18, 1925). We reproduce here a few figures taken from Luengo and de Buen's work (*Arch. de Card. y Hemat.*, Octubre, 1922).

[15] If one takes into account two cases of adult visceral leishmaniasis observed in Tunisia by Lemierre, Leon Kindberg, and Etienne Bernard, and by Burnet and Masselot, it is possible to estimate at sixty-nine the number of cases of tunisian kala-azar, described since 1904 (first case: Laveran and Cathoire) until the month of June, 1925.

The following is the distribution per age of the sixty-nine cases observed:—

Less than 1 year	10
From 1 to 2 years	24
,, 2 to 3 ,, ...	13
,, 3 to 4 ,, ...	5
,, 4 to 5 ,, ...	5
,, 5 to 6 ,, ...	6
,, 6 to 7 ,, ...	2
,, 9 to 10 ,, ...	1
At 26 years	1
At 39 years	1

See *Soc. méd. des Hôp. de Paris*, avril 3, 1925; *Bull. Soc. Path. exotique*, mai 13, 1923.

A comparison may be drawn with the Italian cases (Jemma, Longo, Di Cristina, Caronia, &c.), Greek and Algerian cases.

[16] Dr. Camacho Alejandre has established with precision the small "domestic" centres of visceral leishmaniasis which originated in Almuñecar (prov. of Granada), in farms and country houses, even very distant from each other. Vilá and Torrademè have observed, too, that certain localities (Perelló, Fullola) always furnished more numerous cases than others. Jemma and his collaborators have made the same observation in Palermo, and later in Naples. See, for example, A. Javarona, "Cronaca della leishmaniose infantile a Napoli e dintorni" (*La Pediatria*, No. 15, vol. xxviii, 1920). A few cases of infection of two brothers are reported by the staff of our anti-paludian service and one case of infection of the mother (23 years) and her child has been observed by Ortega in Talavera de la Reina.

[17] The sickness befell a child belonging to a well-to-do Madrid family, who had stayed during the summer at a farm in the province of Almeria.

[18] Of twenty dogs examined by Torrademè (spleen, liver) Vilá diagnosed only in two cases the presence of leishmania. Of forty-five examined by Vilá himself two cases only proved positive.

[19] Leishmaniosis canina (*La Medicina Valenciana*), año xvi, Junio, 1916, No. 185.

[20] De Buen has studied the characters of the parasite-bearing cells of the spleen (*Arch. de Card. y Hemat.*, January, 1923).

[21] See in particular Franco's works (Lisbon), 1922.

[22] In the case of a patient, aged 46 years, published by Vilá (*Rev. Clinica de Madrid*, December 30, 1914), we have ourselves discovered forms of leishmania in the peripheral blood. In a 13-year-old patient de Buen has observed the same fact.

[23] The Commission for studying kala-azar in India, constituted on May 18, 1921, consisted of Colonel S. R. Christophers (president), Captain Barraud (replacing Major F. W. Cragg, deceased), and a protozoologist (Major H. E. Shortt). This commission has just published its preliminary report. From the latter certain facts, which have to be considered final, may be deduced. They can be summed up as follows:—

(*a*) The researches undertaken in Golaghat and Madras with the object of establishing or rejecting the possibility of a direct or indirect transmission of the leishmania by the intestinal canal, or by contact in general, have given absolutely negative results. The hypothetical part played by the intestinal helminths, chiefly *Ankylostoma duodenale*, in such a transmission, has equally been rejected.

(*b*) The parallel researches pursued by Major R. Knowles and Dr. Napier, at the School of Medicine in Calcutta, proved (October, 1924) that the phlebotomes (in particular *Phlebotomus argentipes*, a species peculiar to British India) can infect themselves through biting people suffering from kala-azar, and exhibit in the mesogast protozoan parasites very similar to the flagellated type of leptomonas, which represent, as we know, the leishmania's stage of development in mediums of artificial culture.

These conclusions have been confirmed in Assam by the members of the Commission (January, 1925). Twenty-five per cent. on an average of the phlebotomes fed on kala-azar patients' blood will become, after a few days, bearers of flagellated protozoa of this type.

(*c*) These researches give, of course, nothing definitive as to the actual transmission of leishmania. A very difficult task

still remains to be accomplished with a view to avoiding spontaneous infections of the protozoa-bearing insects; to explaining the passage of the virus into the organs of the insect and establishing the duration of the evolutive circle, &c.; to proving, at last, in the experimental way, that the phlebotomes bearing those forms of flagellated protozoa, may, indeed, infect healthy persons and transmit to them leishmania. This discovery is very interesting, especially if compared with the demonstration given by Sergent of the possibility of inoculating through the phlebotomes the "bouton d'Alep," viz., a cutaneous form of leishmaniasis.

[24] The study of the leucocytarian formula is commonly practised in all the cases of leishmaniasis observed by our school, before puncture of the spleen and as a complement of leucopenia, and for which we are always searching and which is indeed more frequent than one thinks, and almost constant. Now, there is always an eosinophilia, or a very reduced figure of eosinophiles.

[25] The study of ankylostomiasis has been pursued this year in Spain by a commission of the Rockefeller Foundation, conducted by Dr. C. Bailey, aided by Drs. Ortiz de Landazuri and Pacheco, and our resident physician, Dr. Oquineña. I recall here the question of the possible coincidence of ankylostomiasis and kala-azar, because the Commission presided over by Christophers in India had made it one of the subjects of its researches.

An Epidemiological Consideration of the Transmission of Kala-azar in India (L. E. Napier, *Indian Medical Research Memoirs*, February, 1926).—There is considerable evidence in favour of the hypothesis that man forms an essential link in the endless chain of kala-azar transmission, but the hypothesis is not proven. There is very strong evidence that the disease cannot be spread without the aid of an intermediate host, but again the case is not proven. The transmitter is probably a blood-feeding arthropod; on epidemiological grounds only it seems most probable that it is a member of either the genus *Phlebotomus* or the genus *Culicoides*. In the case of most arthropods which have been suggested as possible transmitters of the disease there are numerous epidemiological observations which negative the suggestions, but in the case of *Phlebotomus argentipes* every single epidemiological observation appears to be in keeping with the theory that this insect is the transmitter of the causative organism of kala-azar. Although it is possible that at some future date our knowledge of the geographical distribution and habits of other species of arthropod may point to still other possible hosts, at the present time on epidemiological grounds *Phlebotomus argentipes* can claim the first place in the list of possible transmitters of kala-azar. The obtaining of a more exact knowledge of the distribution of *Phlebotomus argentipes* in the Indian Empire appears to be a most important step towards proving that this insect is the transmitter of kala-azar in India.

BUSINESS AND GENERAL.

1.—The address of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE is Messrs. BALE, SONS AND DANIELSSON, Ltd., 83-91, Great Titchfield Street, London, W.1.

2.—Papers forwarded to the Editors for publication are understood to be offered to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE exclusively, and if accepted the Author thereof transfers any copyright therein to the Publishers of the Journal.

3.—All literary communications should be addressed to the Editors.

4.—All business communications and payments, either of subscriptions or advertisements, should be sent to the Publishers of THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE. Cheques to be crossed The National Provincial Bank, Ltd.

5.—The Subscription, which is Thirty Shillings per annum, may commence at any time, and is payable in advance.

6.—Change of address should be promptly notified.

7.—Non-receipt of copies of the Journal should be notified to the Publishers.

8.—The Journal will be issued about the first and fifteenth of every month.

TO CORRESPONDENTS.

9.—Manuscripts if not accepted will be returned.

10.—As our contributors are for the most part resident abroad, proofs will not be submitted to those dwelling outside the United Kingdom, unless specially desired and arranged for.

11.—To ensure accuracy in printing it is specially requested that all communications should be written clearly.

12.—Special Notice.—Papers can only be illustrated by special arrangement. In order, therefore, to avoid delay, all those desiring to have their papers illustrated are advised to communicate direct with the Publishers at the earliest possible moment.

13.—Authors of original communications are entitled to 25 reprints, free of charge.

14.—Authors desiring additional reprints of their communications to THE JOURNAL OF TROPICAL MEDICINE AND HYGIENE should communicate with the Publishers.

15.—Correspondents should look for replies under the heading "Answers to Correspondents."

Tropical Medicine and Hygiene

DECEMBER 1, 1926.

YAWS IN THE PHILIPPINES.

IN a recent number of the *Philippine Journal of Science*[1] seven of the eight papers which appear are devoted to the subject of yaws. In the first Lopez-Rizal, Gutierrez and Fernandez describe a field experiment in the control of yaws, giving the results

[1] *The Philippine Journal of Science*, vol. xxx, No. 4, August, 1926, containing: "A Field Experiment in the Control of Yaws," L. Lopez-Rizal, P. Gutierrez and L. Fernandez. "A Serological Estimate of the Efficacy of Neosalvarsan in the Treatment of Yaws in a Field Dispensary," R. J. Navarro. "Investigation of Immunity in Yaws," G. R. Lacy and A. W. Sellards. "Superinfection in Yaws," A. W. Sellards, G. R. Lacy and O. Schöbl. "Some Protean Manifestations of the Skin Lesions of Yaws," O. Schöbl, A. W. Sellards and G. R. Lacy. "The Globulin Precipitation Reaction in Yaws. Its Independence of the Wassermann Reactionand its Behaviour during the Course and Treatment of the Disease," O. Schöbl and J. Ramisez. "A Clinical Modification of Yaws observed in Patients Living in Mountainous Districts," L. Lopez-Rizal and A. W. Sellards.

obtained by the Philippine Health Society since the opening in 1921 of a dispensary in Parañaque, Rizal Province, for the purpose of investigating the feasibility of extending yaws campaigns throughout the Philippines. Sixteen years have elapsed since the specific action of salvarsan in yaws was first demonstrated in Ceylon by Castellani, and in the Philippines by Strong, and this has been abundantly confirmed since then. Although so potent and effective in the treatment of yaws, salvarsan is wholly ununsuited for routine work under field conditions. These objections however, do not apply to neosalvarsan and all known cases in Parañaque, as revealed by a house-to-house canvas, having been treated with it. The dosage was approximately 0·01 grm. per kg. of body weight, although a slightly larger dose was given to children and infants, who seemed to tolerate the drug better. The patients received from one to seven injections. During approximately four years 1,151 cases were treated, with the gratifying result that yaws has been brought under complete control in a district which has been heavily infected from time immemorial.

The intermittent operation of yaws dispensaries was found to be an unsatisfactory procedure for the control of the disease in very heavily infected communities. Intensive treatment and persistent vigilance, so as to ensure complete recovery of existing cases, is the most important factor in the control of the disease.

Navarro employed serological measures to estimate the efficacy of neosalvarsan in the treatment of yaws. Accepting as an established fact that the Wassermann reaction is constantly and strongly positive in the active secondary stage of yaws Navarro assumed that the Wassermann reaction was positive in the cases before the treatment with neosalvarsan. Over 80 per cent. were negative from three months to three years after the cessation of treatment and more than half of these had received only one injection. The very brilliancy of the results of a single injection of neosalvarsan carries with it some measure of disadvantage in that many patients do not trouble to return for further treatment.

Investigating immunity in yaws Lacy and Sellards found that reinfection with yaws after treatment by neosalvarsan usually resulted after six months either with characteristic or atypical manifestations, whilst after two years three out of four cases showed well-marked resistance to reinfection. It would thus appear that active immunity develops late in the secondary stage of yaws.

Many points of similarity between yaws and syphilis have been noted, and it is well established that a typical chancre cannot be produced in a patient already infected with syphilis. An investigation was undertaken by Sellards, Lacy and Schöbl to determine whether superinfection is possible in yaws, with the result that in all of five reinoculated patients typical granulomata appeared at the site of inoculation, showing that, in contrast to syphilis, superinfection in yaws is possible, even after the typical primary granulomata have developed. Discussing some protean manifestations of the skin lesions of yaws Schöbl, Sellards and Lacy have shown that the skin manifestations of *Treponema pertenue* are almost as varied as those produced by *T. pallidum*.

Schöbl and Ramirez found the practical value of the globulin precipitation reaction as a confirmatory test of clinical diagnosis of yaws in the pre-Wassermann stage, and as a useful reaction for the guidance of the extent of specific treatment is strongly indicated.

Describing a clinical modification of yaws observed in patients living in mountainous districts Lopez-Rizal and Sellards point out that yaws is widespread in the mountains of northern Luzon, at elevations varying from approximately 600 to 2,100 metres. The disease is endemic in the mountains and propagates itself independently of any communication with inhabitants from the yaws centres of the lowlands.

Clinically, the yaws occurring in the mountainous districts shows a striking peculiarity in that the cutaneous lesions in the majority of the patients (90 per cent.) are limited to the muco-cutaneous junctures of the mouth, nose, anus and genitalia. It would appear difficult to explain this peculiarity in the distribution of the cutaneous lesions, since generalized enlargement of the lymphatic glands indicate the systemic distribution of the causal treponemata.

F. E. T.

Annotations.

Studies on Regeneration of Bacteriophage. The Influence of Oxygen Upon the Behavior of Bacillus Coli towards Lytic Principle (G. Schwartzmann, *Journal of Experimental Medicine*, June 1, 1926).—The investigations of the influence of oxygen on the bacteriophage show that this factor plays an important rôle which is due exclusively to its ability to induce certain changes in the behaviour of bacterial cells towards lytic principle. At certain H-ion concentration, both aerobic and anaerobic cultures can be made resistant in the absence of lytic principle. The resistance thus acquired is of a stable nature under suitable conditions. If the lytic principle is added to aerobic or anaerobic types of resistant strains the cultures are able to regenerate it to a certain extent. However, they do not undergo any visible lysis themselves even under the action of lytic principles which were passed through several generations of these types. The principles regenerated by both types of resistant cultures are identical in action with each other as well as with the stock lytic principle. These experiments suggest a new method of investigation into the hitherto unexplained nature of resistance of bacteria towards bacteriophage.

The Epidemiology of Pneumonia (*a Study of Pneumococcus Carriers among four groups of persons over a period of months*) (J. P. Powell, R. M. Attwater, and L. D. Felton, *American Journal of Hygiene*,

July, 1926). — The purpose of this investigation was to study the distribution of pneumococci among normal persons, the persistence of the organism in the respiratory tract, the virulence of the organism, and the existing relationships between the carrier state and season, age, sex and occupation. This study covers 418 observations on ninety-three persons in four groups—high school boys, medical students, student nurses and laboratory workers all living in the same city and during the same period. There is good evidence that very few persons can long escape contact with some form of the pneumococcus under the conditions of ordinary life. Moreover, contact with one of the fixed types of pneumococcus forms associated with 80 per cent. of all cases of pneumonia is demonstrated for half the group during a period of seven months. Presumably, then, practically everyone at sometime during the course of a year is a carrier of a fixed type of pneumococcus. Waves of unusual prevalence of the fixed types of pneumococci are described. These were not accompanied by corresponding cases of pneumonia in the same group. The figures for that year, in Boston, indicate that there was about one case of pneumonia for every 175 residents during the period of investigation. This group consisted of ninety-three persons, so that the fact that only one person developed the disease was within expected limits. The prevalence of carriers of the different types of pneumococci, chartered by months, suggests that we are dealing with organisms that go through seasonal variations in prevalence, variations which are probably different for the several types of the pneumococcus. The study of virulence by months also suggests that we are dealing with a biologic function of the parasite, analogous to well known seasonal activities in the plant kingdom. Study of the persistence of pneumococci in the respiratory tract of carriers shows that at least the fixed type organisms tend to disappear from the mouth and throat in less than thirty days. This was true in thirty-seven instances out of forty-five carriers who were found with these organisms. There was one instance in which a Type III pneumococcus was found in a person over a period of at least 120 days and there is reason from virulence studies to believe that this was persistence rather than reinfection. Three other cases showed persistence of from sixty to ninety days, but these were exceptions. Type IV pneumococcus shows a persistence which is regarded as apparent rather than real, because of the variability in virulence of successively recovered strains and also because of the multiple opportunities for reinfection with indistinguishable strains of this type. There appears to be no significant difference between the sexes in their tendency to become carriers of the pneumococcus. The four groups of persons show evidence that their mutual associations favour local contact and their pneumococci tend towards a uniform distribution of types within each group at one time. When normal persons carry fixed types of pneumococci, they are rarely able to give any clue as to the source of these pathogenic varieties, a fact that has been brought out before. These observations confirm the fact that persons in contact with cases of pneumonia more frequently carry fixed type pneumococci in their throats than controls, but carriers of fixed types are rather frequent among the population at large. Persons may also get their pneumococci from contact with carriers. Therefore the isolation of cases of pneumonia could not be expected to be more than partially effective in controlling the disease. Studies on the virulence of 216 strains, isolated during this investigation and tested on white mice, indicate that Types I and III tend toward a higher level of virulence than Types II or IV. In comparison with another study made in Boston and during the same year, there is observed an essential consistency of the virulence in all types recorded excepting Type II, in which an unusual number of avirulent strains were encountered. The findings in this study, when compared with similar material from other sources, show an essential consistency. In this composite fashion the data on carriers of pneumococci among 895 normal persons are given by types. Another comparison of data from 868 persons in Boston shows the definite excess of carriers among normal persons exposed to cases of pneumonia. In general these data serve to confirm the view that the disease pneumonia appears when there is a coincidence between infection with a pathogenic form of the pneumococcus and a lack of resistance in the same individual.

A Case of Giardia Intestinalis treated with Stovarsol (J. L. Pawan, *Annals of Tropical Medicine and Parasitology*, June 24, 1926).—Dobell states that emetine and methylene blue have no effect upon *Giardia intestinalis* or any of the other "common intestinal flagellates." Oral administration of salvarsan is said to have cured cases in human beings, by Bavant, Carr, and Chandler, and in mice and rats, by Rogers, Kofoid, Yakimoff and others, but Dobell finds the evidence for cure in these cases inconclusive. "It appears probable," he says, "from the evidence at present available, that no specific treatment for infection with any species of intestinal flagellates has yet been discovered. When negative examinations are made during or after a course of 'specific' treatment, they cannot be regarded as evidence of 'cure' unless they extend over a period much longer than any 'negative period' which may be observed in any untreated cases." In the case recorded examination of the fæces on January 26, 1926, i.e., twenty-eight days after the last 'negative' examination, still showed no *Giardia*."

Evaluation of the Methods of Stoll and Lane in Light Hookworm Infections and Accuracy in Diagnosis of the Willis Flotation Method (W. C. Hausheer, C. A. Herrick and A. S. Pearse, *American Journal of Hygiene*, July Supplement, 1926).—In a series of seventy carefully studied stools the regular Stoll technique (large drop) will detect cases having as low

as fifty eggs per grm. by Lane count, if not less than two slides are examined. Lane's method, pushed to finality, demonstrated 68·3 per cent. of the ova indicated present by the regular drop dilution egg-count, and diagnostically showed every Stoll positive. The small drop Stoll technique demonstrated 94·5 per cent. of the ova shown present by the regular dilution counts. The small drops failed diagnostically (two slides only being counted from each tube) in 75 to 80 per cent. of cases having less than 200 ova per grm., but showed high diagnostic efficacy in the higher counts. An analysis is presented of the Willis flotation method, and its efficacy when properly handled is emphasized. It would appear to be as accurate as Lane's direct centrifugal flotation when certain details in its use are observed.

The Relation between the Age and the Virulence of Cultures of Bacillus Aertrycke (Mutton) (G. S. Wilson, *Journal of Hygiene*, July, 1926).—Four batches of sixty mice were injected with comparable doses of *B. aertrycke* (Mutton) taken from broth or agar cultures in different phases of reproductive activity. The mortality and the average survival time of the mice after injection varied so little amongst the different groups as to justify the conclusion that no difference in the virulence of this organism is detectable during the first week of growth.

The Further Development of Onchocerca Volvulus Leuckart in Simulium Damnosum, Theob. (D. B. Blacklock, *Annals of Tropical Medicine and Parasitology*, June 24, 1926).—Larvæ of *O. volvulus* taken from the skin by *S. damnosum* in biting, undergo progressive development in the fly and finally reach the proboscis; the time taken to complete the development depends largely upon temperature.

The shortest period which elapsed after feeding before the proboscis became infected was seven days. The mature larvæ are found in the labium of the fly and escape through the membranous portion of it. In so far as experiments with wild flies can be accepted as evidence in the absence of transmission to man or animal, *S. damnosum* is a vector of *O. volvulus*.

A Study of the Incidence of Kala-azar in certain parts of North Behar. (D. F. Michael, *Indian Medical Research Memoirs*, July, 1926).—Kala-azar is endemic in the districts of Darbhanga and Muzaffarpur. Certain villages are foci of infection, notably the villages of Rampur Bakhri, in the Muzaffarpur District and possibly also Mahespur in the same district and Mahanada and Malinagar on the Darbhanga side. The villages forming the eastern, western and southern boundaries of Bakhri are slightly infected as judged by the number of cases reported, while Mahanada on the north side appears to be fairly heavily infected—exemplifying "site infection." Lack of conservancy, defects in domestic and personal hygiene and the presence of dirt in and around houses are apparently definitely connected with the prevalence of the disease. The institution of hygienic measures in an infected area combined with the treatment of cases of the disease seems to lessen the incidence in a striking manner. The disease is most prevalent when humidity is relatively high and markedly less during dry weather. Children and young adults to a slightly less extent show the greatest susceptibility. In this connection it is worth while to note the comparative immunity to the disease which people of the sweeper class enjoy. Not a single case has, to the author's knowledge, occurred amongst either the hospital sweepers or the Pusa Estate Conservancy Establishment or their families during the past four and a half years, while children of other servants in attendance on the sick in hospital have contracted the disease.

Observations upon Hookworm Disease in Mexico (H. P. Carr, *American Journal of Hygiene*, July Supplement, 1926).—It has been shown that hookworm disease in Mexico is confined to certain areas, and the limits of these areas have been determined. The incidence of hookworm disease in this area and the average individual infestation has also been determined. There was a high degree of negative correlation between the egg-count and the hæmoglobin of groups of individuals belonging to the labouring class in Mexico. There was no difference in the average hæmoglobin of groups of individuals, whether they showed no hookworm infestation by the egg-count method or whether they showed a very light infestation by the same method. Evidence has been presented which indicates that the predominant species of hookworm in Mexico is *Necator americanus*.

Hookworm Reinfestation for Three Years after Treatment in a Sanitated Area in Porto Rico and its Bearing on Permanent Hookworm Control in the Group Studied (R. B. Hill, *American Journal of Hygiene*, July Supplement, 1926).—A quantitative study, by the use of the dilution egg-count method, was made on a group of approximately 300 people in a sanitated area in Porto Rico before and just after treatment, one year after treatment, and three years after treatment. Treatment reduced the incidence from 90 per cent. to 19 per cent. of the people. The rate rose rapidly the first year, less rapidly thereafter to 58 per cent. after three years. The intensity of infestation was reduced 98 per cent. by treatment and this rose to 20 per cent. of the original infestation in three years. Farmers showed the greatest absolute increase, children under ten years of age the greatest relative increase. In neither group was the infestation heavy after a period of three years. It is concluded that sanitation and intensive treatments have given results of permanent value in the control of hookworm disease in Porto Rico.

The Action of Hepatic Extract in Hypertension (R. H. Major, *Journal of the American Medical Association*, July 31, 1926).—As previously stated, it is still felt that definite conclusions regarding the action of hepatic extract in hypertension can be drawn only after a large number of patients have been treated over a long period of time. The evidence, at the present time, that the liver extract is effective in certain cases of arterial hypertension is very suggestive but is not conclusive.

The Place of the Smear in Hookworm Diagnosis (W. C. Hausheer and C. A. Herrick, *American Journal of Hygiene*, July Supplement, 1926).—The smear method is diagnostically accurate if the intensity of infestation is such that 500 or more ova are present per grm. of fæces. The smear method, if only two slides are examined for a negative, will fail in a certain percentage of cases yielding between 300-500 per grm. of stool. If less than 300 ova are present per grm. of stool the smear is highly inaccurate. When the above factors are taken into consideration the smear method may be used with confidence; it is simple, rapid, and still holds a valuable place in the fæcal examination for hookworms.

A Proposed Method of Laboratory Evaluation and Classification (J. B. Peterson, *Journal of the American Medical Association*, July 24, 1926).—A laboratory classification of mercury compounds has been made by measuring their inhibiting effect on the yeast-sugar fermentation. All the values were compared with their inhibiting value of mercuric chloride. The inhibiting effect of the yeast-sugar fermentation in most cases is due to the mercuric ion concentration, although in some cases other components of the solution are concerned. Molecules identical with flumerin, mercurochrome and metaphin, except for their respective mercury carrying groups, show considerable inhibitory power. The inhibiting value of crystal violet, methyl violet and gentian violet has been measured and compared with the inhibiting value of mercuric chloride. It is recognized that the work of classification of substances, particularly antiseptics, according to their behaviour, chemical, bacteriological and clinical, is far from complete.

Reviews.

THE BIOLOGY OF THE PROTOZOA. By Gary N. Calkins, Ph.D., Professor of Protozoology, Columbia University. Illustrated with 238 engravings. London: Baillière, Tindall and Cox. 1926.

It was a heterogeneous mass of microscopic living organisms which was revealed to the scientific world by van Leewenhoek in the seventeenth century from which the protozoa, microscopic single-celled animal forms, have been gradually differentiated, although even at the present day we are unable clearly to differentiate them from multicellular vegetable organisms. It was to avoid this difficulty that Haeckel introduced the term protista to embrace all unicellular organisms, but, as Calkins remarks, this is merely another name for the aggregate and an artifice for concealing the real difficulties which we would like to overcome.

In the work before us the author tells us that he has brought together the conclusions founded on thirty years of research on the protozoa and on an equal number of years of teaching protozoology, and ventures to hope that the presentation may be a step towards the unification of the various phases of protozoa-study and a suggestion of a common point of view in protozoology.

He deals first with the distribution and general organization of the protozoa, with their structural differentiations and their nuclei and kinetic elements, and then with their general physiology, discussing their life organization and vitality and the functional activities of the individual. Then follows a chapter on reproduction, including both unequal division (budding or germination), whether exogenous or endogenous, and multiple division or spore formation.

One chapter each is devoted to a description of the special morphology and taxonomy of each of the four great groups of protozoa, to wit, mastigophora, sarcodina, infusoria, and sporozoa, after which follow chapters on vitality, on the phenomena accompanying fertilization and the effects of reorganization and the origin of variations in the protozoa.

Throughout the volume one underlying biological principle has been constantly kept in mind, namely, the irritability of protoplasm, combined with protoplasmic organization.

The various types of organizations which form the basis of classification are systematically described, keys being added to assist in placing the commoner genera.

The fundamental vital functions are treated as manifestations of vitality. Life and vitality are treated as independent concepts—life as organization, and vitality as the activity of the organization. The various phases of vitality—youth, maturity and old age—are consequences of changed or changing organization through continued metabolism, whilst death is the disintegration of the organization.

Dr. Calkins is to be congratulated on having produced a great zoological volume, which must prove of immense value to the serious student of protozoology in its more zoological aspect, who will derive great benefit, not only from the author's descriptions but also from the numerous keys and well-executed diagrams, from the extensive references supplied, as well as from the exhaustive indexes, both of authors and subjects, which complete this masterly volume.

VARIATIONS IN THE VIRULENCE AND IN THE MORPHOLOGY OF CERTAIN LABORATORY STRAINS OF *TRYPANOSOMA GAMBIENSE* AND *TRYPANOSOMA RHODESIENSE* ISOLATED FROM HUMAN CASES.

By J. G. Thomson, M.A., M.B., Ch.B.,
Director of the Department of Protozoology,
and
Andrew Robertson, M.B., Ch.B.,
Assistant in Protozoology, London School of Hygiene and Tropical Medicine.

Introduction.

Since the discovery of trypanosomes as the cause of disease in man numerous observations have been made on human strains when inoculated into laboratory animals, as regards the virulence they display, and also the morphological changes which occur in the new host. *Trypanosoma gambiense* and *Trypanosoma rhodesiense* can probably be inoculated successfully into most mammals, although those used most commonly for experimental purposes are rats, mice, guinea-pigs, rabbits and monkeys, but they certainly show decided differences in their virulence. Thus *T. gambiense* is frequently by no means easy to isolate in rats, and, even when infection has been established, the first few passages commonly produce a disease in the animals of an extremely slow, chronic nature. On the other hand, it is usually a comparatively simple matter to produce an initial infection in rats with *T. rhodesiense*, which, after a few subinoculations, becomes an acutely fatal disease. It is also well known that in such experimental hosts as rats, &c., the morphological characters of the two species under discussion alter considerably. These differences in virulence and animal reactions in general have been so exhaustively studied and noted in the literature by Bruce and Coll (1903), Thomas and Linton (1904), Laveran (1908), Brumpt and Wurz (1904), Beck (1910), Bentmann and Günther (1907), Yorke (1910), and others that it is not intended to deal in this paper with the subject in its entirety, but rather to draw attention to one or two important details which have not been thoroughly explained.

Duke (1921 and 1922) brought forward some interesting observations regarding the unity or plurality of species of the African polymorphic trypanosomes, and, while avoiding anything in the nature of a dogmatic attitude, he advanced the hypothesis, strongly supported by his personal experience and experimental work, that there was only one true species. He points out that good species are based on their morphological characters, not merely on certain peculiarities due to physiological or environmental variations, and that, in the event of the differences, say between *T. gambiense*, *T. rhodesiense* and *Trypanosoma brucei*, falling within the limits of such variation, they could be regarded, from the systematic point of view, as "races," "strains," or "varieties" of a single species. In other words, if *T. brucei* is the species, then *T. rhodesiense*, *T. gambiense* and *Trypanosoma nigeriense* are to be regarded as particular strains of that species, so-called "physiological variants." The same author (Duke 1923) suggests the possibility of *Trypanosoma evansi*, *Trypanosoma equinum* and *Trypanosoma equiperdum* having originated at some time from the polymorphic group, that, as a result of prolonged mechanical transmission, the trypanosomes have assumed different morphological features. Possibly the cyclical transmission in the tsetse-fly keeps the trypanosomes true to type, and this must be borne in mind when dealing with laboratory strains which are mechanically transmitted from animal to animal. Duke also advances the view that the polymorphic trypanosomes of Africa owe their present differences largely to the influence of the vertebrate on which, in the course of time, they have become dependent as their main blood-host.

These views, stated so clearly and ably by Duke, have undoubtedly occurred to other workers. In the present instance, when dealing with five distinct strains isolated during recent years from four human cases, four of which were *T. gambiense* and one *T. rhodesiense*, certain interesting facts have been elicited showing that, with the passage of time, strains, mechanically transmitted, may change entirely in their morphological characters, and, further, that under certain conditions, which will be specified later, the typical morphological features of the original strain can be obtained again.

Variations in the Virulence to Laboratory Animals of Strains of Trypanosomes from Human Cases.

It is now a well-established fact that rats are comparatively refractory to the initial inoculation with *T. gambiense* from human cases, while later the virulence may become remarkable. On the other hand, the subsequent history of the strain may show that the virulence increases slowly, and, even after a considerable number of passages, may produce a disease in rats characterized by its chronicity. Both these points are well illustrated in the histories that follow

Strain H (*T. gambiense*) was isolated from a patient, H. (European), aged 26 years, who had become infected at Mabang in the Sierra Leone Protectorate. Following discovery of trypanosomes in his blood on December 27, 1918, he returned to this country, and was admitted to hospital on February 15, 1919, when the organisms, though not numerous, were still present in his blood. On February 20, 1919, two rats each received intraperitoneal injections of 2 c.c. of blood, and in a few days' time, trypanosomes appeared in their peripheral blood.

Thereafter the strain was easy to maintain, and its virulence rapidly increased. One point, however, ought to be noted, the strain was not maintained solely in rats, but guinea-pigs were frequently

interposed in its lineal passage. The strain was kept going in the laboratory for about two years, at the end of which time the virulence had increased to such a degree that rats succumbed in from two and a half to three days, and guinea-pigs in a week or less.

Meantime the patient H, having become discontented in hospital, had departed before his cure was established, but in October, 1920, owing to a recrudescence of symptoms, he returned for further treatment. On this occasion trypanosomes were found to be still present in his blood, and accordingly two rats were inoculated on October 8, 1920. One of these rats died in a few days' time from an intercurrent pneumonic condition; the other never showed trypanosomes, but, on May 6, 1921, six months after the original inoculation, it was killed, and its heart-blood inoculated into two other rats. Trypanosomes appeared in one of these animals in five days' time, and this was the origin of Strain H2.

TABLE SHOWING LINEAL DESCENT OF STRAIN H2.

Number	Source of infection	Date of inoculation	Date of death	Number of days' incubation	Duration of infection in days
1	Patient	8. 10. 20	6. 5. 21	—	210

22	21	7. 7. 23	10. 12. 24	20	,, 300

By referring to the table showing the lineal descent it will be seen that Strain H2 was maintained through twenty-two direct passages over a period of just over four years. To begin with the virulence was very slight, but, after the sixth subinoculation it showed signs of increasing. It will be noticed also that the period of incubation, by which is meant the number of days which elapsed between the inoculation and the appearance of the organisms for the first time in the peripheral blood of the animal, was decreasing in similar manner. At this point a guinea-pig (Animal No. 7c) was introduced into the line of descent, and this was followed by a rise in the virulence (Animal 8b), reducing the incubation to ten days and killing the rat in seventeen days. Thereafter, with a few slight variations, the incubation period remained wonderfully constant at from eight to ten days, whereas the duration of the infection, i.e., the length of time between the inoculation and the death of the animal, became progressively longer and longer. Trypanosomes were by no means constantly present in demonstrable numbers in the blood of the animals towards the end of the table, but would appear for a few days and then their numbers would gradually tail off again to remain absent sometimes for months. The animals, at this stage of the strain, showed practically no symptoms of disease except towards the

end, when the fatal termination was usually foreshadowed by a marked increase in the number of trypanosomes and their non-disappearance from the peripheral blood.

The patient J. (European), from whom Strain J, *T. gambiense*, was recovered, had received his infection in the Upper Kwilu district of the Belgian Congo. He arrived there in 1919, and was quite well until January, 1920, when he had a few days fever, which, at first, was supposed to be of malarial origin. Blood-films, however, examined a few days later, demonstrated the presence of trypanosomes, and, accordingly, he came home to be admitted to the Hospital for Tropical Diseases on May 31, 1920. Two rats were inoculated the following day intraperitoneally with approximately 2·5 c.c. of the patient's blood.

In parenthesis it may be mentioned that the patient, after a prolonged course of treatment, relapsed, but was eventually discharged apparently cured. It would appear that his infection was of comparatively low virulence, and the disease was of the chronic variety.

TABLE ILLUSTRATING STRAIN J.

No.	Source of infection	Date of inoculation	Date of death	Number of days incubation	Duration of infection in days
1	Patient	1. 6. 20	17. 1. 21	15	221
1a	Patient	1. 6. 20	19. 10. 20	15	140
2	1a	19. 10. 20	26. 10. 21	12	372
2a	1a	19. 10. 20	23. 4. 21	16	186
5	4	11. 10. 21	10. 2. 22	13	122
7	6	22. 2. 22	23. 8. 22	7	182
12	11	17. 10. 22	6. 2. 23	6	112
17	16	9. 2. 23	30. 5. 23	10	110
21	20	24. 7. 23	20. 12. 23	9	149
23	22	8. 8. 23	12. 8. 24	21	283
25	24	30. 7. 24	7. 1. 25	41	161
27	26	5. 4. 25	6. 9. 25	16	154
27a	26	7. 9. 25	27. 2. 26	8	173

The subsequent history of the strain is of interest chiefly on account of the fact that, after the expiration of just over five years and after twenty-seven direct passages, when it was discontinued, the virulence had not altered materially. It will be seen from the accompanying table, showing the particulars of the first and last animals and of a few intervening animals chosen at random, that there was little difference in the period of incubation or in the duration of the disease. A further characteristic of this strain was that about fifteen days, as a rule, after the inoculation trypanosomes appeared in the peripheral blood of the animals, and, although they were in fairly considerable numbers, they disappeared again in from one and a half to three days, and did not reappear until the end of the infection. This is well exemplified in the case of the first two rats (Nos. 1 and 1a), which were inoculated from the patient on June 1, 1920. On June 16, fifteen days later, they both showed trypanosomes. Rat No. 1a, in which the organisms had never returned, was killed on October 19, and its heart-blood was inoculated into another two rats (Nos. 2 and 2a), both of which showed trypanosomes in twelve and sixteen days respectively. Rat No. 1 was allowed to live, and eventually trypanosomes were discovered late in November, five months after the original discovery in the peripheral blood.

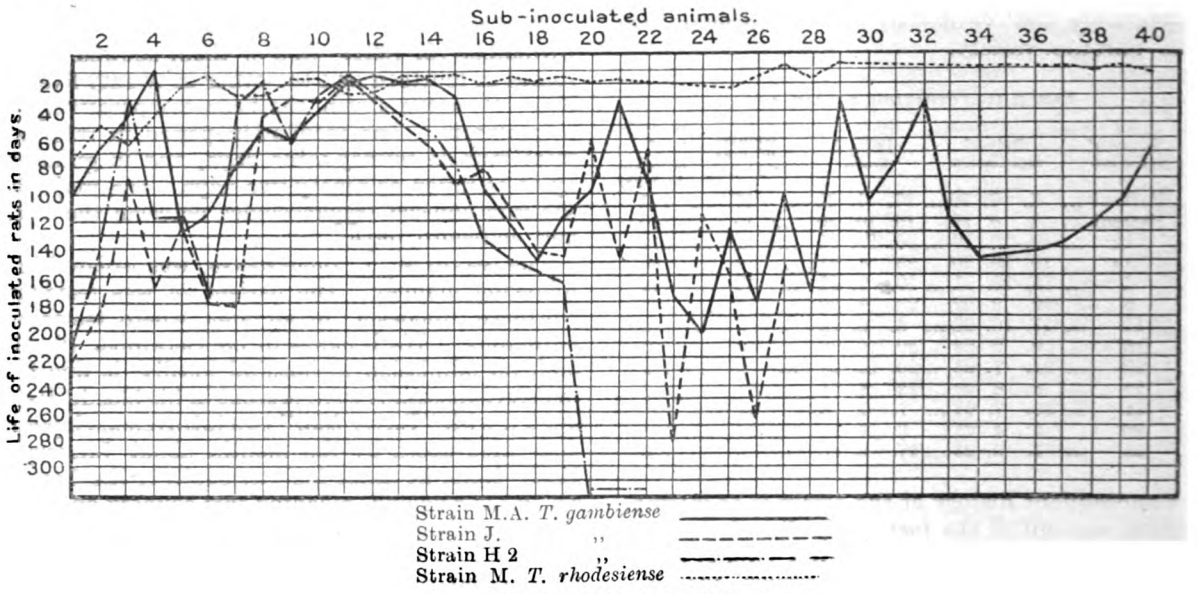
The history of the Strain MA, *T. gambiense*, differs in certain particulars from all the foregoing, Strains H, H2 and J. The patient (European), aged 49 at the time of his admission to hospital, had been for some years in a tsetse-free area of Northern Nigeria. In March, 1921, he removed to Southern Nigeria, to an area where tsetses were present, and, although no history of having been bitten was obtainable, he developed fever in July, 1921. It was at first thought that he was suffering from rheumatic fever, but on his admission to the Hospital for Tropical Diseases, November 5, 1921, trypanosomes were found to be present in his blood-stream. He was finally discharged from hospital on March 3, 1923, having been treated first with " Bayer 205 " and then with atoxyl and antimony.

Two rats were inoculated from the patient on November 10, 1921. One of them showed trypanosomes in fourteen and the other in twenty-five days. Since then the strain has been comparatively easy to maintain. The incubation period in rats varied from four to twenty-three days, and in guinea-pigs up to as much as ninety-two days. The majority of the rats showed trypanosomes between the twelfth and sixteenth days.

The Strain M, *T. rhodesiense*, was isolated in the following manner. The patient M was resident in Northern Rhodesia, in an area where tsetse were numerous. He became ill on December 10, 1921, and, on admission to hospital locally, it was found that trypanosomes were present in his blood. He was treated with "Bayer 205," two intravenous injections and three doses by the mouth, about January 14, 1922. Later he made his way south to the Cape and sailed for England, reaching this country on April 6, 1922. On June 8, 1922, he was admitted to the Hospital for Tropical Diseases, and, as he was found still to be harbouring trypanosomes, he received a course of " Bayer 205 " during June, July, August, up to September 18, on which date he was discharged from hospital, no trypanosomes having been found in his blood since June 13. On November 3 he was readmitted, and, despite the fact that " Bayer 205 " was pushed to the limit, he died on January 7, 1923.

During December, 1922, and January, 1923, a series of experiments were carried out with urine from the patient, to determine the effect of the injection of urine from a case undergoing treatment with " Bayer 205 " on rats inoculated with a strain (not the patient's own strain) of *T. rhodesiense* (Thomson and Robertson 1923).

On January 4 two rats were inoculated with blood from this patient, and on January 6 a rat was inoculated with some of his cerebrospinal fluid. One of the rats inoculated with blood died as a result of the inoculation, but the other showed trypanosomes in five days and lived for seventy-five days from the date of inoculation. The rat



which had the cerebrospinal fluid lived for seventy-four days, trypanosomes having appeared in six days.

A comparison of the relative virulence of the foregoing five human strains, Strains H, H2, J, and MA, *T. gambiense*, and Strain M, *T. rhodesiense*, elicits certain interesting features. It is unfortunate, however, that in the case of Strain H, *T. gambiense*, a complete record of the strain is not now available; the important point with regard to it is that in two years its virulence had increased to a remarkable extent, and at the same time had also become stabilized. That is to say, it killed rats regularly in three days.

In the accompanying graph an attempt has been made to represent the virulence of the four strains. For this purpose the length of life of the animals after inoculation has been taken as giving an approximate indication of the virulence of the strain. In the graph the ordinates represent the subinoculated animals, and the abscissæ the duration of their life in days after the date of inoculation. Thus the shorter the life of the animals the higher the peak of the virulence. It will be seen that the curves of the three *T. gambiense* strains follow an almost identical course. There is, to begin with, a sharp rise reaching the peak about the third or fourth subinoculation, but falling just as sharply at the fifth, six and seventh. The virulence of all three rises again to form a sort of plateau, roughly between the eighth and twelfth passages. The decline from this plateau is gradual up to the nineteenth animal. After that point the Strain H2 became very avirulent, and, indeed, was only carried on through three more sets of rats, Nos. 20, 21 and 22, when it was discontinued. The other two strains, i.e., Strains J and MA, *T. gambiense*, on the other hand, followed a swinging course, the virulence practically alternating with each passage between what may be termed the two extremes. Strain J was tending also to become rather avirulent, and it was dropped at the twenty-seventh passage. More recently the Strain MA has lost, to a large extent, its swinging character, and has killed the animals in between eighty and one hundred and twenty days.

In marked contradistinction to these *T. gambiense* strains the *T. rhodesiense* very soon attained a fixed virulence, which has been steadily maintained ever since.

It seems a curious coincidence the way in which all three strains follow such parallel courses. There may be no special significance attached to it, and no explanation is attempted. That it is due, perhaps, to outside influences seems unlikely, since the dates on which the various subinoculations were performed did not correspond in any way and the animals were obtained from time to time from different sources.

For explanation see text.

Alterations in the Morphological Characters of the Strains after a Series of Mechanical Transmissions.

All the strains of *T. gambiense* and *T. rhodesiense*, including other strains not specified in the foregoing sections, which have been maintained in the department during recent years, have shown certain alterations in their morphological characters, which have resulted in the production of forms somewhat similar to those found in infections with *T. evansi* and *T. equiperdum*. In other words, instead of showing a well-marked polymorphism they have become after a varying number of passages, to all intents and purposes monomorphic, with the prevailing form, the long, thin trypanosome with a conspicuous free flagellum. Strain H, at its most virulent stage, was a good example of this state of

affairs. Of the other three strains, Strains H2, J and MA, in which the virulence was comparatively low, the polymorphic character was lost much more gradually; indeed, in the Strain MA it can still be recovered easily by side-tracking the strain from rats through a guinea-pig. It is interesting to note that in the Strain H2 forms appeared early in the series of passages indistinguishable from the short forms (about 8 microns in length) which have been described in connection with the so-called *T. nigeriense* variety of *T. gambiense*.

The Strain M behaved in the fashion usually found with strains of *T. rhodesiense*. That is to say, it showed during the first few passages the well-known polymorphic characters with occasionally posterior displacement of the trophonucleus in the short, stumpy forms. As the strain grew older these posterior-nuclear forms were seen more and more rarely, until they finally disappeared at the eighteenth passage from the rats, and, in the case of guinea-pigs in which the strain was being carried on parallel to the rats as a temporary measure, at the twelfth passage. The polymorphic nature gradually went also, but this could usually be brought back again by inoculating from the rats into guinea-pigs, although it only once has been possible—after the eighteenth rat passage—to bring back posterior-nuclear forms by this means. The occasion referred to, when the posterior-nuclear forms returned, occurred at the forty-fourth passage, after fourteen direct passages through rats.

This Strain M, because of its standard virulence, was being used at various times to test the effect of drugs as trypanocidal agents (the findings in this respect will be the subject of a separate communication). This question is introduced here because it was found that, after treatment with some of the drugs, posterior-nuclear forms were found to return. It seems suggestive that posterior-nuclear forms appear in a *T. rhodesiense* strain, when first isolated from a human case, will return when the strain passed direct through one species of laboratory animals is diverted into another species, and also can be made to reappear through the action of chemicals. The drug may act in one of three ways: it may act on the parasite, on the host, or on host and parasite together. The most feasible explanation, from our previous knowledge of the action of drugs in trypanosomiasis, seems to be that the drug has so altered the host and the resistance of host to organisms that the condition is analogous to the state of affairs produced by direct inoculation from one vertebrate species to another. The first drug to cause this return of posterior nuclear forms was one of a series of three arsenic compounds (arsenic in combination with a complex organic radicle) which were, judging by the length of life of the treated animals and the course of the infection in comparison with controls, of very slight trypanocidal effect. This reappearance occurred about the twentieth passage of the strain. At the forty-first passage they occurred in a rat treated with a substance called bistoval (bismuth acetylamino-oxyphenylarsinate), which is also very low as regards its curative value. Again, about this time posterior-nuclear forms reappeared on treating infected rats with tryparsamide. Lastly, while treating rats with halarsol (4-oxy-3 amino-phenyldichlorarsine) posterior-nuclear forms appeared in several animals; indeed by its use these types could be made almost to return at will.

The results of these curative experiments cannot be given in detail here, but it is germane to the present purpose to indicate one peculiar effect they have in altering the virulence of the strain. This may be exemplified by citing the cases of rats which had received a dose each of tryparsamide on the first day the organisms were found in their peripheral blood, that is to say, in the early stages of the disease. Very soon after the curative dose the organisms disappeared from the peripheral blood and remained undiscovered for about five months. At the end of that time one of the animals was killed and trypanosomes were found in the heart-blood and also in the brain. The other animal showed trypanosomes about a month later, and died shortly after. The manner in which the drug, given in the early stage of the disease, alters the virulence from a rapid, acute action to a slow, chronic one is most striking, and it is felt that this mode of action of drugs, especially the arsenicals, should be taken carefully into account by those engaged in the treatment of human cases (cf. Case H indicated above). Another detail worthy of emphasis is that after treatment and while in the chronic state the animals may carry trypanosomes in the central nervous system without showing symptoms. Halarsol-treated rats also have shown this change to a chronic state, and, in parenthesis, it may be said that of all drugs tried this, apart from "Bayer 205" and tryparsamide, is the only one which has shown really encouraging results.

Discussion.

It has been shown clearly that the initial transmission by mechanical means of *T. gambiense* and, in lesser degree, of *T. rhodesiense* from a human patient to laboratory animals, in the present instance rats, may be attended with certain difficulties. That there does exist a decided resistance to infection is well illustrated by the histories of the four strains of *T. gambiense* quoted above. In the Strain H2, for example, the first rat inoculated from the patient lived for six months, without showing trypanosomes in its peripheral blood, and it was only by a further passage that the trypanosomes became sufficiently numerous to be demonstrable. Thus it would appear that, as an aid to rapid diagnosis of trypanosomiasis in man, the inoculation of suspected blood into laboratory animals is a procedure the value of which is most problematical. There is no intention to suggest that it may be impossible to infect laboratory animals with *T. gambiense* from man, but rather to emphasize the peculiar latency which the organisms may exhibit in the new host. Wenyon (1926), discussing the pathogenicity of trypanosomes, states that the human strain of *T. brucei* (*T. rhodesiense*)

is easily inoculated from man into rats, in which it rapidly becomes virulent, "whereas *T. gambiense* in these circumstances may fail to infect the rat, though it usually does so, leading to a chronic type of infection characterized by the presence of a small number of trypanosomes in the blood at any time, the animals surviving for a year or even more." The occasions on which *T. gambiense* did not produce an apparent infection in rats possibly might be explained on the basis of a "latent" infection, a condition which can be compared aptly to "cryptic" trypanosomiasis.

This difficulty in establishing an infection in a new host (i.e., a host of a different species) is not confined to *T. gambiense*. Thus *Trypanosoma vivax*, as a rule, will not infect rats and guinea-pigs, but it has been shown by Blacklock and Yorke (1913) that rabbits under certain circumstances could be inoculated. *Trypanosoma congolense*, again, shows remarkable variations in its initial virulence (Yorke and Blacklock, 1923), some strains being virulent immediately, while others may become so only after many passages. Bruce and Coll (1913) report a most curious condition. Working with *Trypanosoma simiæ*, they found that the parasite was very fatal to monkeys, and while goats were susceptible, it was only in a much less degree. On attempting to inoculate back again from a goat to a monkey the latter proved to be refractory, indicating that passage through the goat had markedly decreased the virulence. On passing *Trypanosoma pecorum* through goats it was found also that it had lost its virulence to rats. Taute and Hueber (1919) inoculated themselves and 129 natives with blood from four horses and two mules containing trypanosomes like *T. rhodesiense*, and, apparently, failed to establish an infection in any of the human hosts, although controls, dog, goat, and rats, were infected. In this connection Yorke and Blacklock (1922) state as their opinion "that the majority of human beings is resistant and only occasionally susceptible to infections with trypanosomes," and, further, that "the experiments (of Taute and Hueber) simply confirm us in our belief in the relative immunity of man to infection with *T. rhodesiense*"

It would thus appear that the conclusion—that the human variety *T. rhodesiense* is distinct from the *T. brucei* of animals—arrived at as a result of this huge experiment of Taute and Hueber is open to criticism. In the first place there is the undoubtedly difficult factor of the transmission from one vertebrate host to another host of a different species to be overcome, and, secondly, there is the possibility that infection of the "latent" or "cryptic" variety analogous to that found in the initial transmission of *T. gambiense* from man to rat might have resulted. Had Taute and Hueber carried their experiment a step further by subinoculating blood from their original 131 into other human hosts the result might have been most interesting.

This state of affairs, in which trypanosomiasis is more or less dormant, is closely paralleled by that which sometimes follows drug treatment. In human patients there often may be clinical cure, the organisms may disappear from the peripheral blood, but exist in the cerebrospinal fluid. Attention was drawn to this phenomenon by Kleine (1924), who, by making lumbar punctures, found trypanosomes in eight out of twenty-one patients, about three months after the commencement of treatment with "Bayer 205." These patients displayed no symptoms, and their blood was free from parasites. The effect of drugs on experimental animals (carrying the Strain M, *T. rhodesiense*) in certain instances has been very similar to that in Kleine's group of cases. In one experiment in which the drug used was tryparsamide the animals lived for many months, and at death trypanosomes were found in the brain and heart-blood. While not attempting to indicate that this is the only or even the main mode of action of such drugs, it certainly seems possible that the character of the host has been so changed by the action of the drug as to produce a condition similar to that obtained by inoculating from a host of a given species into one of another species.

As a general rule mechanical transmission of a strain of trypanosomes results in a steady increase in virulence, until eventually the parasites become stabilized in their artificial host. The passage of such a strain from one host to another of a different species may render the parasites more deadly in their action. On the other hand, it may not do so. Thus if a strain of *T. gambiense* is kept in rats, transferred to a guinea-pig, and then by passage reintroduced into rats, at first it may be less virulent, but soon it may exhibit a greater virulence than previously. Thomas and Breinl (1905) found that a strain of *T. gambiense*, after passage through a baboon, showed an enhanced virulence to rabbits rats, cats, guinea-pigs and monkeys. In the present series mechanical passage of the Strain M, *T. rhodesiense*, resulted in a marked increase of virulence and rapid stabilization; the four *T. gambiense* strains on the other hand, showed marked differences, and, in one instance (Strain H2) even became progressively less virulent. Comparing Strain H with Strain H2, the latter having been isolated about two years after the former, there is, in this matter of virulence, a huge discrepancy. The suggestion is, therefore, that the patient H, during his period of treatment, was altered as a host, was rendered less susceptible, and lapsed from the acut condition into a state nearer approximating to that state of balance in which apparent harm is done neither by parasite to host nor *vice versa*, in brief into chronic, latent or almost cryptic trypanosomiasis. In any event the duration of its residence in the human host, or the action of drugs on host or parasite, had modified profoundly the virulence of the strain to laboratory animals.

As regards the morphology, continued direct transmission of one of the polymorphic group results in what is tantamount to monomorphism *T. gambiense* and *T. rhodesiense* gradually lose the short, stumpy forms and the intermediate forms, finally ending up as long, slender trypanosomes with a conspicuous free end to the flagellum.

Should there be passage into another species of host, whose susceptibility is very nearly but not quite the same as the original host, there is a tendency for the polymorphism to return. The degree to which the polymorphism will return may be influenced perhaps by the proportionate difference which may exist between the susceptibility of the hosts, i.e., the greater the resistance in the new host the more likely is the return. By transferring *T. gambiense* or *T. rhodesiense* from rats, in which the polymorphism has been lost, to guinea-pigs, the shorter forms can be made to return. The same effect, but in even more conspicuous degree, can be obtained in rats by means of drug treatment. It must be clearly understood that it is not intended to indicate that, after a series of mechanical transmissions, the trypanosomes will always continue to revert to their original state of polymorphism; their ability to do so becomes decidedly less and less the longer the strain is kept and the more numerous the passages. It is desired to emphasize that the tendency towards polymorphism is definitely aided by transmission into another species of host even by mechanical means, and that by the injection of drugs, a similar condition is brought about within the same species of host.

Edwards (1926), in an interesting paper, drew attention to the fact that in India surra is a very severe disease in equines. In bovines, on the other hand, *T. evansi* is much less virulent, buffaloes especially developing almost a complete tolerance to this trypanosome. Evidently, however, in certain localized areas sometimes it may acquire an increased virulence even to the buffalo. No adequate explanation has been advanced so far for these local epidemics, and, as surra normally is propagated by mechanical transmission, this factor cannot be incriminated as the cause of the outbreaks. With regard to African sleeping sickness, it has been suggested by Duke that the reason why the disease from time to time assumes epidemic proportions is to be found in the increased virulence resulting from rapid mechanical transmission. It is felt that mechanical transmission alone, even rapid transmission with alternation from the usual host, the wild game, to man, is insufficient to explain the sudden and devastating nature of the outbreak. It is within the bounds of possibility that the increased virulence might be due to the passage of the organisms through some special host, a host in which they may not produce any unusual virulence, but which might alter their future reactions in man.

Conclusions.

(1) *T. rhodesiense* can be inoculated easily from man to rats. In Strain M parasites appeared in the blood of the rat five days after the injection of human blood. Strains of *T. rhodesiense* rapidly increase in virulence, and, by subinoculation, soon become stabilized. Strain M became stabilized soon after the sixth passage.

(2) *T. gambiense* is much more difficult to establish in rats. Strains H2 and J took months to show in the peripheral blood of the original rats.

(3) *T. gambiense* may become rapidly virulent to rats (cf. Strain H, which soon became stabilized, eventually killing rats in three days); on the other hand, it may become even less virulent by passage, as in the case of Strain H2, in which the twentieth, twenty-first and twenty-second animals lived well over a year each.

(4) The variations in virulence of the three strains (Strains H2, J and MA) of *T. gambiense* followed a similar curve. First there was a sharp rise to the third and fourth passages, then a drop at the fifth and sixth. At the seventh or eighth passage there was a quick rise in virulence, which was maintained for about five passages, i.e., up to the thirteenth. Thereafter the fall in virulence was gradual until the nineteenth passage, when there was divergence.

(5) Two strains of *T. gambiense*, isolated at an interval of nearly two years from the same human case, showed marked variation in their virulence. The first to be isolated (Strain H) became rapidly stabilized, and in two years was killing rats in three days; the second (Strain H2) finally became less virulent, the last three animals all surviving for more than a year.

(6) This discrepancy in the relative virulence of these two strains (H and H2) possibly is due either to the difference of the lengths of time they inhabited the human host, or to the treatment which the patient H had received in the interval before the second strain was isolated.

(7) *T. gambiense* may exhibit a peculiar latency, lying dormant, as it were, in subinoculated rats. This latency has been compared with "cryptic" trypanosomiasis. For example, two rats inoculated with Strain J showed trypanosomes in their blood on one occasion sixteen days after inoculation, and did not show again for about five months. A similar latency may be observed in human cases as a result of drug treatment. When rats carrying the virulent, stabilized Strain M are treated with drugs, especially the arsenicals, the trypanosomiasis similarly may be dormant.

(8) By mechanical transmission a strain of trypanosomes, maintained in a series of hosts of the same species, *usually* will exhibit increased virulence; on the other hand, the virulence may actually decrease, as in Strain H2, *T. gambiense*. By passage through a host of a species different from the usual the virulence of a strain may be markedly modified, either diminished or increased.

(9) It is suggested that in trypanosomiasis, among other actions, drugs may change the character of a host. Further, that such alteration in the host almost may be comparable to that obtained by injecting organisms from a host of the species in which the strain is usually mechanically maintained into a host of another species. This is exemplified in the patient H. Before treatment the organisms isolated from his blood were very virulent; after treatment they became very avirulent to the rats. In rats carrying *T. gambiense* (Strain MA) which were treated with halarsol, the strain rapidly became much more virulent during subsequent passages.

(10) When either *T. gambiense* or *T. rhodesiense* are transferred mechanically from man to rats, at

first the trypanosomes exhibit a well-marked polymorphism, with, in the case of the latter, the appearance of posterior-nuclear forms, but later this is lost. Up to a certain stage the polymorphic nature of the parasites can be made to return by transferring the strain from the usual host into a host of another species.

(11) A return of the polymorphism and, in the case of *T. rhodesiense* posterior-nuclear forms, can be brought about by the action of drugs. The suggestion is that the return to the polymorphic character is not due so much to the action of the drug on the parasites as on the host.

Tropical Medicine and Hygiene

DECEMBER 15, 1926.

THE TREATMENT OF TROPICAL SORE.

Cutaneous ulcerations of granulomatous nature are prevalent in many warm countries, in which, however, they usually appear to be endemic within certain limited areas. This local prevalence has caused various local names to be applied to this

condition in large numbers, as evidenced by the following synonyms which have been employed for this condition, namely: Delhi boil, Aleppo boil, Biskra boil, Baghdad boil, ulcera du Bauru, bouton d'Orient, ulcère d'Orient, chancre du Sahara, dermite ulcéreuse circonscrite, Endemische Beulenkrankheit, bottone d'Orient, Godownick, Il-jarassy, Tschiban, Dous-el-Kourmati, Ghisud, Habb-es-Sanawi, Habb-es-Sanah, Bess-el-Temur, Salek, Pascha-churdj, Afghan jara, Jaman dyscharagan, Taschkent jarassi, Taschkent ulcer, mycosis cutis chronica, lupus epidemicus, endemic boil disease, granuloma endemicum, furunculus orientalis, Pianbois, parasitic granuloma, Sudan nodules and Leishman nodules.

To cover all this multiplicity of names for what is essentially one and the same condition the terms oriental sore and tropical sore have been employed. As, however, the disease is always manifest as a cutaneous lesion produced by a definite specific infection by a species of Leishmania, a better and more suitable name for this condition is cutaneous leishmaniasis. The genus to which this species of organisms belongs was created by Ross in 1903, under the name of Leishmania, which is defined by Castellani and Chalmers as "Herpetomoninæ, living principally in endothelial cells, but also found in leucocytes and in the peripheral blood of mammals as small, oval cytoplasmic masses with trophoand kineto-nuclei, and developing into flagellate bodies in cultures."

Three species are known to occur in man, morphologically similar but pathologically different, namely: *Leishmania donovani* Laveran and Mesnil 1903, causing kala-azar; *Leishmania infantum* Nicolle 1908, causing infantile splenomegaly; and *Leishmania tropica* Wright 1903, with its variety *Leishmania americana*, causing cutaneous leishmaniasis or tropical sore and espundia or mucocutaneous leishmaniasis.

The infectivity of this organism has been definitely proved by direct inoculation both in man and animals.

Neither race, age, sex, occupation nor social condition materially affects susceptibility to infection. Insect-carriers have long been subject to suspicion, but up to the present no insect has been definitely demonstrated to be the true host of *Leishmania tropica*.

After an incubation period variously stated in days, weeks or months ulceration of the skin commences and slowly extends so that it may eventually occupy an area several inches across, though usually it presents a diameter of about one inch. After a period varying from two to twelve months, or even longer, healing commences by granulation, but the process is often slow and interrupted. Healing is eventually complete, but much scarring may result. It would appear that a tropical sore produces a definite immunity, so that, as a rule, second attacks do not occur.

Many and various are the forms of treatment which have been advocated for this condition. Excision of the sore has been advised. Various antiseptics have been employed topically, either as lotions, powders or ointments. These include perchloride of mercury, carbolic acid, permanganate of potassium, tincture of iodine, boric acid, silver nitrate, protargol and methylene blue. Salvarsan and atoxyl have been used without any good result. Ionization, X-rays, light treatment and carbon-dioxide snow have all been more or less favourably reported upon. More recently good results have been recorded from the injection into the base of the sore of gradually increasing doses of emetine hydrochloride.

The most successful results, however, have resulted from the use of tartar emetic, which has been described as a specific for this condition, and of phosphorated oil. The former is best administered in the form of intravenous injections, using a one per cent. solution in saline solution or in distilled water. It may also be given by intramuscular injection, but this method suffers from the drawback that solutions of tartar emetic, as of other antimonial salts, are painful and apt to induce the formation of abscesses. Tartar emetic may also usefully be administered orally, especially in conjunction with intravenous or intramuscular injections. Lastly, tartar emetic may be applied locally as a one per cent. ointment or a one per cent. lotion, but the local application of tartar emetic in powder, which has been recommended, should be avoided on account of its extreme painfulness.

Phosphorated oil in the form of the oleum phosphoratum of the British Pharmacopœia, was first advocated by Castellani in 1923. He observed that the use of this preparation by subcutaneous injection was practically painless, and provided small doses were employed there was no risk of phosphorus poisoning—either immediate or delayed. Good results have been recorded from its use in cases of tropical sore. It is essential that the phosphorated oil should be of recent preparation. Its mode of employment is as follows: When the ulceration is well marked the oil is applied directly to the fundus and margins of the ulcer after removing the scab, and this simple treatment alone was found to answer admirably in cases recently recorded by Kelaart. When the lesion is a nodular one and there is little ulceration, in addition to the direct application of the oil subcutaneous injections should be given. In carrying these out a sterile 20-minim all-glass hypodermic syringe is used; three to five minims of the recently prepared phosphorated oil are drawn into the syringe and then injected into and around the lesion by inserting the needle of the syringe into the nodule and under the skin round its margin; two or three drops of the oil are then dabbed on the surface of the ulcer. This procedure is repeated once or twice a week, according to the amount of local reaction which ensues. If this is severe, which only very occasionally happens, the injections should be discontinued for a time and hot boric fomentations should be applied.

Subcutaneous injections of phosphorated oil have also been employed in other conditions such as rickets and osteomalacia, and, as an adjuvant to

quinine and arsenic, in certain cases of chronic malarial cachexia. It has further been suggested that this method of treatment might also be tried and might be found of benefit in other forms of leishmaniasis, as well as in certain cases of ulcer of non-leishmania origin, as, for example, granuloma inguinale, ulcus tropicum and certain persistent tropical ulcerations of obscure origin.

Finally, it may be pointed out that phosphorus possesses powerful poisonous properties, and that its special tendency is to damage the liver, which, though it may be a delayed result, should never be lost sight of. The administration of oleum phosphoratum, therefore, always demands the exercise of the greatest care, and in its use every possible precaution should be taken.

F. E. T.

Annotations.

The Cultivation of Herpetomonas muscarum (*Leidy* 1856) *Kent* 1881 *from Lucilia sericata* (J. J. Drbohlav, *The Journal of Parasitology*, June, 1926).—A herpetomonas requiring a medium of low hydrogen-ion concentration, i.e., pH 5·6 to 6·4, was isolated in pure live culture from the green-bottle fly, *Lucilia sericata*. It was found in 83·4 per cent. of the specimens examined. On account of the group specificity of herpetomonads obtained from muscoid flies, and from the results of Becker's and other experiments, as well as from their morphological identity, they are considered to be of the species *Herpetomonas muscarum* (Leidy 1856) Kent 1881. This species should be considered as uniflagellate. In division a precocious growth of the second flagellum gives the impression that the parasite is biflagellate. Forms without nucleus found also in pure culture may be explained on the basis of atypical division. Large multinuclear forms, without multiple nuclei and parabasal bodies developed in cultures, being sometimes ten times as large as usual. These probably result from a failure of the cleavage of the cytoplasm to keep pace with nuclear division. No intracellular forms of *H. muscarum* were found. The failure to find this species on microscopical examination of the ovary or in cultures inoculated with ovarian tissue, indicates that it is not commonly transmitted through the egg of the fly.

Emetine Periodide in the Treatment of Schistosoma hæmatobium Infections amongst West African Children (R. M. Gordon, *Annals of Tropical Medicine and Parasitology*, August 13, 1926).—An examination of 81 children at the "United Brethren in Christ" Missionary School, Jiama, Nimmi Korro, showed that 43 of them were suffering from *Schistosoma hæmatobium* infection of the bladder; of these 43 cases, 28 were severe cases (passing many live eggs and much blood in every sample of urine examined). These were divided into equal classes. Class I received emetine hydrochloride treatment given subcutaneously; Class II, emetine periodide treatment given by the mouth. The average age of the emetine hydrochloride group being eleven years and six months, and that of the emetine periodide group nine years and seven months. The result of the treatment seems to be quite uninfluenced by the age of the child.

The oral administration of emetine periodide cleared up the urine of children intensely infected with *S. hæmatobium*, just as quickly and almost with as great certainty as subcutaneous injections of emetine hydrochloride. Certain ill-effects were noted as the result of subcutaneous injections of emetine hydrochloride and great difficulty was experienced in making the children report for treatment. No ill-effects followed the oral administration of emetine periodide, and no difficulty whatsoever was experienced in getting the children to attend for, and take, this drug.

Medical Aspects of Life Insurance in India, with Special Reference to Calcutta (E. Houseman, *Indian Medical Gazette*, June, 1926).—The risk of Indian residence is steadily decreasing for both Europeans and Indians. Taken as a whole, Indians are considerably worse risks than Europeans and insurance companies probably act wisely when they encourage endowments rather than whole-life policies for Indians. Indians are usually men of shorter stature than Europeans and their corresponding weights generally are lower. This is particularly noticeable in the younger men, but older men are inclined to become heavier than Europeans. Indians who are overweight should be regarded unfavourably, they are generally prosperous, lead sedentary lives, and eat carbohydrates to excess.

Respiratory diseases, and more particularly pneumonia and phthisis, are very fatal diseases for Indians. The phthisis mortality shows no tendency to decline and the disease is usually of a very acute type. It is more fatal for women than men, probably owing to the *purdah*. Dysentery and bowel complaints are very fatal for Indians, but the mortality from these diseases has declined considerably during the last thirty years. The mortality from fevers declined rapidly in Calcutta up to 1908, since when it has remained fairly constant. Hydrocele is especially prevalent amongst Indians and is an occasional cause of death. Glycosuria is not very prevalent amongst Indians until they reach middle age, after which its incidence increases and it becomes more fatal for Indians than for Europeans. Indians tend to have a higher blood-sugar than Europeans. Owing to the infrequency of acute rheumatism and scarlet fever, valvular disease of the heart is not so common amongst Indians as among Europeans, but malignant endocarditis and myocardial degenerations are common. Pyorrhœa is very common amongst Indians, so much so that after middle age few seem to be free from it.

Principles in the Testing of a Cure (H. W. Acton, *Indian Medical Gazette*, June, 1926).—Cures may

be of two kinds, permanent or temporary. In the latter condition the causative agent of the disease is still present, but not in sufficient numbers to give rise to symptoms. Permanent cures may occur with complete recovery of the tissues, or may be incomplete with impairment or loss of function. In every test of a cure, the data of composition of the population tested should always be given as regards its important ætiological factors such as age, habits and customs, &c., since these factors may profoundly influence the course of the disease. The two populations compared, those under test and the controls, should be similar in every respect; e.g., with regard to numbers, homogeneousness, &c. The percentage mortality or cure-rate is obtained by observations on 100 individuals; not by elevating observation on digits into percentages. A homogeneous population under test can only be secured by avoiding bias, and paying attention to the law of chance sampling. The testing and control experiments should be carried out under identical conditions in order to avoid obtaining the results of only partial correlations. Also tests for a cure should, if possible, be carried out in non-infective areas, with regard to protozoal diseases especially, in order to exclude the chances of re-infection. Only differences between the two groups of a significant order should be considered; e.g., those outside the range of chance sampling, or partial correlation.

The permanency of a cure can only be tested by time, the continued well-being of the patients, and the effect of the introduction of the cure on the mortality rate for a given disease in the general population. In cases of rare diseases, where large numbers of observations are not possible, one has to rely on diseases which show chronicity before treatment, high mortality rate, and the rapid disappearance or arrest of the diseases when under treatment. The relative value of a modification of treatment, e.g., of the comparative value of the dry cord method and the dilution method of Hoghyes in anti-rabic treatment, or of the different pentavalent compounds of antimony in the treatment of kala-azar, can only be tested on a large scale. Consideration must also be paid to the relative toxicity to the body of the different compounds used, apart from the therapeutic value.

Studies on the Serology of Leprosy. III. The Kahn Precipitation Reaction in Leprosy (E. V. Pineda and E. R. Pineda, *The Philippine Journal of Science*, July, 1926).—One hundred non-leper sera, obtained from the venereal clinic and outpatient department of San Lazaro Hospital, were examined for the Wassermann and Kahn tests. There was an agreement in the results of 93 per cent. One hundred leper and leper-suspect sera were tested by the Wassermann reaction and by the precipitation test of Kahn. There was very close agreement in the results of the Wassermann and Kahn test, with a slight sensitiveness in favour of the Kahn test. The Wassermann and the Kahn tests in leper patients are generally negative. There was observed in 1 per cent. of leper and leper-suspect sera, positive Wassermann reaction without any history or signs of syphilis or yaws. In confirmed leper sera, the Wassermann test was positive in 1·23 per cent. of the cases without any signs or history of syphilis or yaws. Kolmer and Denny found that 7·32 per cent. of non-syphilitic leper sera gave falsely positive Wassermann reaction. The Kahn test was positive in 5 per cent. of leper and leper-suspect sera without any signs or history of syphilis or yaws. In confirmed leper sera, the Kahn test was positive in 6·17 per cent. of the cases without any sign or history of syphilis or yaws. As far as lepers are concerned, the Kahn test is of greater value than the Wassermann test in excluding syphilis or yaws, and of less value in establishing the diagnosis of these two diseases.

The Deodorization of Coconut Oil (W. L. Brooke, *Philippine Journal of Science*, June, 1926).—Methyl-nonyl-ketone was isolated from the product obtained from the deodorization of coconut oil, thus confirming the finding of Haller and Lassieur. Its presence is established by the preparation and identification of the oxime, dioxime and semicarbazone. Most of the non-saponifiable substances distil over in the first few hours of deodorization. The yields of the non-saponifiable constituents obtained from crude coconut oil in the laboratory and from the condensed deodorization sludge that was obtained from the factory are described by the author. The non-saponifiable constituents also contain alcoholic compounds. Two analyses of the crude acid sludge are also described.

Current Literature.

THE AMERICAN JOURNAL OF TROPICAL MEDICINE. July, 1926.

Developments in Anthelmintic Medication (M. C. Hall).—Up to less than half a century ago anthelmintic medication underwent a very slow evolution, then there was a rather rapid acceleration in the way of developments, and the last ten years, which covers critical experimental investigations, is considered the third stage in the development of this subject. Anthelmintics were first given consideration centuries ago, when natives associated the passage of worms with foods and other substances previously eaten, and many kinds of plant material came to be recognized as anthelmintic in nature. The oldest anthelmintic now in use is the male fern, known to the ancient Greeks. It was used in the Middle Ages and then appears to have been forgotten until the eighteenth century, when it was restored to use. Interest was revived in anthelmintics on the discovery of the human hookworm, *Ankylostoma duodenale* (Dubini, 1843), but the first serious consideration was not until 1881, when Perroncito tested male fern and other anthelmintics on

hookworm larvæ *in vitro*, and on the results with male fern administered this drug to human patients with a fair degree of success. In the same year Bozzolo proposed thymol which became the standard drug for the treatment of ankylostomiasis, and held this position for a quarter of a century. In 1904 beta-naphthol was proposed by Bentley, and is still in use. Favourable reports were received from Brazil on the use of chenopodium in the treatment of ascariasis, but its use was not favoured in Europe until 1913, when Schuffner and Verwoot gave chenopodium an adequate test in ankylostomiasis and reported favourably on it. In the following decade it took first place and was used extensively. In 1921 carbon tetrachloride was proposed by Hall for the removal of hookworms and was used with great success. In 1925 a new drug was proposed by Hall and Shillinger, tetrachlorethylene, a chemical closely related to carbon tetrachloride, claiming that it is safer and more effective than the latter. Recent developments along the lines of correlation of egg-counts with worms present by the methods of Stoll and Clayton Lane have materially added to the accuracy of testing the value of anthelmintics, but this is still an open field for investigation and promises definite and valuable results.

Some Atypical Cases of Yellow Fever in Salvador (H. Hanson).—Yellow fever epidemics appear to be no exception to the rule that there are always some cases in epidemics in which the so-called classical symptoms are missing. The author describes four cases which occurred in the recent outbreak of yellow fever in San Salvador, Central America. Three of these cases had been vaccinated with the Noguchi vaccine against yellow fever and they were all taken sick within fourteen days after the second inoculation, i.e., before the elapse of the period required for the establishment of immunity. The three cases presented a mild type of the disease. The other case had not been vaccinated and presented the type of the disease with cerebral manifestations which usually is fatal. The symptoms rapidly subsided after the intravenous administration of Noguchi anti-yellow fever serum. The important points in the treatment of these cases involved (1) complete rest in bed; (2) starvation; (3) catharsis; (4) administration of water, in small quantities and frequently; (5) seclusion of the patient. Morphine or quinine should never be used in yellow fever therapy.

Histoplasmosis of Darling with Report of a Case Originating in Minnesota (W. A. Riley and C. J. Watson).—Histoplasmosis of man has been known hitherto only from the three cases reported by Darling, from Panama. A fourth case is reported —that of a woman who had not been out of the State of Minnesota in forty-two years. The case was clinically identical with those reported by Darling: greatly enlarged spleen, pseudo-granuloma of the lungs, emaciation and anæmia. In phagocytic cells of the lung, liver, spleen and lymph nodes were enormous numbers of the organism described by Darling under the name *Histoplasma capsulatum*. As pointed out by Da Rocha Lima (1912), this organism is evidently closely related to *Cryptococcus farciminosus* Rivolta, the cause of epizootic lymphangitis of horses and man. While Da Rocha Lima and most recent workers regard this organism as a yeast, Ota (1925) places it in the genus *Grubyella*, among the hyphomycetes. Most of the mycoses which become systemic are rapidly fatal. This condition was systemic and chronic for many years. The available evidence does not support the view that histoplasmosis of man is identical with epizootic lymphangitis. In clinical picture and in size and morphology of the organisms, it differs from the torulosis of Stoddard and Cutler, cases of which had been noted especially in the vicinity of Chicago, Illinois.

The probability is that in histoplasmosis and in epizootic lymphangitis we are dealing with two very closely related species of *Cryptococcus* (Grubyella), one causing systemic infection and one largely superficial. An analogous situation is afforded by *Leishmania donovani* and *Leishmania tropica*. The finding of this case emphasizes the importance of considering the possibilities of the disease in connection with obscure cases of splenomegaly in temperate as well as in tropical zones.

Observations on the Emergence of Anopheles Mosquitoes (G. H. Bradley).—During the mosquito breeding seasons of 1921, 1922 and 1924 observations were made near Mound, Louisiana; a total of 904·9 square yards of water surface in selected anopheles breeding areas was covered by nets and 585 adult anopheles, emerged therein, making an average daily emergence of 0·653 per square yard. The nets were located in areas which showed a higher larval rate, as determined by larval counts, than is generally found in the anopheles breeding areas of the region. An increase in the number of larvæ present in the selected areas did not cause a proportionate increase in the rate of emergence. This may have been caused by a scarcity of suitable food in the concentrated areas, or by the activities of certain enemies of the larvæ. The females of anopheles were found to emerge in somewhat greater numbers than the males. A discussion is given showing that this condition is usually met with among anopheles, although approximately equal numbers of the sexes have been observed at certain times, and at others, a large preponderance of males has been recorded.

Observations on Dientamœba Fragilis (R. Kudo).—A case is recorded in which *D. fragilis* was found in the stools of a patient in Urbana, Illinois. This protozoan was first observed by Wenyon, 1909, and has since been found in cases in England, New York, Holland, Manila, Hamburg and Baltimore. It has been well studied and described by Jepps and Dobell (1918). The number of amœbæ present in this case was very great. Binucleate amœbæ were found in only 12·2 per cent. and uninucleate forms in 87·8 per cent. of 2,000 individuals observed at random. Nuclear division is described.

Colonial Medical Reports.—No. 186.—Bengal (*contd.*).

The inundation of the country during the monsoon is unfavourable to the multiplication of anopheles mosquitoes, in the first place, because flooding reduces the dangerous "water-edge" which affords safe cover for mosquito larvæ; in the second place, because owing to the large surface exposed to the rays of the sun the temperature of the water tends to rise so as to be exceedingly unfavourable to the life of anopheles larvæ; and in the third place, because the physical and possibly the chemical character of river water is inimical to anopheles larvæ. Observations show that anopheles larvæ are rarely or never found far from the grass-grown or weedy edge of collections of water; that they cannot stand a wet temperature much above that of the wet bulb thermometer and are rapidly killed by a temperature of 104° F.; and that they do not flourish in water containing fine silt in suspension. River water in the flood season also contains a very large amount of carbon dioxide (CO_2), so much so that its reaction tends to become acid, and this possibly affords a further explanation of the fact that anopheles larvæ do not flourish in river water during the flood season.

Recent Investigations on the Breeding of Anopheles Larvæ.—Investigations by Hodgson and King serve to throw a new light upon the rationale of phenomena of the kind referred to, enabling us to understand how irrigation may, in certain circumstances, reduce malaria, and why, on the contrary, a reduction of the surface water in deltaic areas may bring about an increase of the disease. The following passage is extracted from Hodgson's note in the proceedings of the Lucknow Sanitary Conference, 1914:

"Taking the mosquito in its larval existence, we found that the optimum temperature for anopheles lay between 68°-78° F. Temperature above 80° F. became more and more unsuitable, while temperatures of 95°-104° F. were rapidly fatal. In nature during the monsoon at Delhi in August, and in Madras in November, we found the surface of pools to vary from 73°-104° F., the difference being due to the following important facts:

(1) The coolest pools were very small pools lying amongst grass.

(2) The edge of the pool in the daytime was cooler than the centre.

(3) The surface layer is often 3° or 4° hotter than the water four or five inches down at midday.

(4) The water lying at the shallow edge, round grass stems, is the coolest part of a pool.

(5) When the average temperature of pools had risen to 90° or even 100°, falling rain, both at Delhi and Madras, was found to be 73° to 77° F. during the monsoon.

(6) The river at Delhi, even after long drought, never rose above 87° F. at midday.

(7) Well water varied from 80° to 82° F.

(8) The sea at Madras in the monsoon was 80° F.

(9) Small hoof-marks in grass might contain water 9° F. cooler than a large pool six inches away, particularly during hot dry weather.

"An anopheles mosquito lays her eggs in that type of pool which is coolest at the time. The struggle for existence rapidly increases above 80° F. and temperatures such 104° F. are fatal to every single larva in less than eighteen hours, though this is a temperature at which some pools have been found in nature. In the Terai in October, water varied from 65° F. to 78° F. on the two days we examined it, and anopheles were breeding in millions. The great destroyer of mosquito larvæ is nature, and her principal means is raising the temperature of the water."

It will be seen from these observations that small collections of water and those possessing a large ratio of weedy edge are far more dangerous than large water surfaces, because they invariably possess a lower temperature much more suitable for mosquito larvæ than the high temperature to which large collections of water speedily become raised. This fact helps to explain the beneficial effect of flooding upon the prevalence of malaria. When water is admitted in large amount to the surface of a low-lying country, all the small pools are converted into large ones; on the one hand the ratio of dangerous edge is greatly reduced, and on the other hand the temperature of the water is speedily raised, with the result that the output of anopheles mosquitoes is restricted.

Indirect Effect of Embankments on Malaria.—Embankments that prevent flooding may thus be a direct cause of malaria, but they also tend to increase the malaria of delta tracts in an indirect manner. The cessation of inundation, as we have seen, causes a decline of agriculture, leading to economic stress among the population. It causes also a coincident increase of anopheles mosquitoes, leading to the spread of malaria infection. The final result is an extraordinary exaltation of malarial disease, signalized by the occurrence of a serious epidemic. This epidemic malaria in turn causes depopulation, partly by increased mortality and reduced fecundity and partly by stimulating migration. And depopulation introduces a further vicious cycle, causing a still further increase of malaria and still greater depopulation, until in badly affected localities the population is eventually either entirely obliterated or reduced perhaps to a tenth of its former number, the sites of once densely populated towns and villages quickly lapsing into almost impenetrable jungle.

Why the Danger of Embankments was not formerly Understood.—When the embanking of the delta tracts was begun, first as a measure of flood prevention, as in the case of Burdwan, Murshidabad and Nadia, then for roads, as in case of Jessore, and finally owing to the construction of railways, few persons realized that the process was fraught with danger. Even after attention had been called to the outbreaks of fever that followed the construction of embankments, the term "water-loogging," which was frequently employed without having been clearly defined, appears to have led to a misunderstanding of the situation. In those days the cause of malaria was unknown, but medical authorities were wont

to ascribe it generally to "water-logging," meaning thereby a super-saturation of the soil with water. Rajah Digambar Mitter, when seeking to explain the epidemics of malaria that occurred in association with the construction of embankments, suggested that they were due to "water-logging," produced by these embankments. By "water-logging," however, he appears to have meant "obstructed flow" rather than super-saturation of the soil. It may be remarked that the term is frequently used by Bengalis in the former sense at the present time. Obviously, obstructed flow may occur either in association with excess or as a result of deficiency of water; but in Bengal it is deficiency rather than an excess of water that is especially dangerous, and that is concerned in particular with the obstructed flow so often observed in the case of the silted-up channels of malarious areas. When, however, the medical men and engineers, who were asked to investigate the epidemic fever, sought for evidence of water-logging, they naturally looked for evidence of the saturation of the soil, which that phrase ordinarily implies, and, failing to discover much evidence of this, they declined to admit that water-logging was the explanation of the epidemic fever; whereas, had they inquired into the question of obstructed flow and a reduction of the surface water in the affected tracts, they would have found, as in fact many of them did find, evidence of this on all sides. Even in comparatively recent times, a similar misunderstanding has often prevented an appreciation of the real facts. Recently a serious increase of malaria in a village near the Sara Bridge followed the shutting out of flood water by the construction of an embankment. In reply to an appeal from the District Magistrate, the engineers who were responsible insisted that the village must in reality have become more healthy, rather than less so, because, owing to the embankment, it was much drier than before. In this case it was true that the village was drier than formerly, but it was also true that the breeding of anopheles had been greatly increased in consequence of the numerous small isolated collections of rain water that had taken the place of the former general flooding of the village site, with the result that malaria had greatly increased.

The Effect of Superabundance of Water on Malaria.—As a matter of fact, few people are aware that for centuries it has been known that the partial drying up of large swamps often renders them intensely malarious, and that in low-lying deltaic tracts a heavy rainfall and the occurrence of inundations prevents malaria and serves to keep them healthy. "In some marshy countries," says Davidson, "a heavy rainfall diminishes the prevalence of fever by covering the marshy ground with a protective sheet of water. Thus, in the Netherlands, it has often been remarked that rainy years are healthy years, while hot and dry seasons are feverish." "Very heavy rain," says Scheube, speaking of conditions affecting malaria prevalence, "has a deterrent influence on naturally damp soil. . . . . At the height of the rainy season. . . . in Deli, in Sumatra (Martin), and New Guinea (Schellong), the minimum number of cases of illness is notified." He explains this by observing that "a thorough soaking of the soil is deleterious to the development of the mosquito." "In many regions," says Craig, "where abundant rains occur, malaria is rare, even though the anophelines are present. This is explained by the fact that in such regions the rains are so heavy and continued that the breeding places of mosquitoes are washed out and ova and larvæ do not have a chance to develop, or that no infected individuals are resident in the locality. In the former instance an unusually heavy rainfall may act as a protection against malaria."

The passages quoted above show that it has long been recognized that in low-lying countries a superabundance of surface water, far from being harmful, may exert a beneficial influence upon malaria. And authorities like the late Professor Angelo Celli and Professor Julius Mannaberg have always regarded flooding or "covering by water" as useful measures for the control of the disease.

Embankments a first step in Reclaiming a Delta.—The first effect of constructing embankments in low-lying areas subject to inundation from rivers is to reduce very largely the total volume of water present on the surface of the land during the actual flood season, which in hot countries is the malarious season. This reduction of the surface water causes a great increase of malaria. The second result is that the amount of rain water that is held up after the flood is over and the water-level of the rivers has fallen, may be considerably increased because the embankments tend to check the "run-off" from the land surface. This does not usually affect malaria very much, because the season of new infections is nearly over, but it damages agriculture. Embankments, therefore, cause an extraordinary change in the entire regime of a delta. Many deltas, it is true, have been reclaimed and put under pasture or dry cultivation; and this reclamation has necessitated the construction of embankments. But it has been necessary in all such cases to provide special systems of drainage, usually by means of pumps. Examples of this are to be seen in the case of the Po, the Rhine and the Scheldt, and in the Fen district of England. The construction of embankments is often therefore a first step in the reclamation of a delta. But deltas that have been embanked without any corresponding reorganization of their drainage are only partially reclaimed. The situation of the population of a delta that has been left in this condition is deplorable in the extreme. Agriculture is seriously interfered with. The cultivators cannot grow the same amount of wet crops as formerly, owing to the lack of fertilizing river silt and the fact that in some portions of the country there is too little water while in others there is actual water-logging; and they cannot grow day crops because drainage by gravity is not sufficient for this purpose. Above all the people are exposed to recurring attacks of epidemic malaria as a result of the partial reclamation of the country by embankments.

Partial Reclamation of Low Lands always conduces to Malaria.—Throughout all ages history is unanimous on this point, that the partial reclamation of swamps invariably leads to an appalling increase of malaria.

"No one in Holland," says Wilson, speaking of the influence of malaria in causing disease, "has any doubt as to the origin of this power, but ascribes it uniformly to the drainage of some lake. . . . It was even foretold by several writers that fevers would result from draining the Lake of Haarlem, as took place in the years 1608, 1641 and 1779 from draining several polders. At Haarlem the summer of 1779 was extremely hot and a fever epidemic appeared which continued for three years. It was ascribed to the draining of several polders." "So long," he adds, "as the Lake of Haarlem was a lake, or mere, so long were its banks healthy. But drain it partially and you must be prepared for the result. There is no middle course. It must be arrested by the hands which drained or attempted to drain it and converted into healthy pasture land or a wheat field. . . . . The effects of partial or incomplete drainage have ever been the same."

The influence of partially reclaiming swamps or lakes on the health of the inhabitants was frequently discussed during the last century, especially in connection with the draining of the low-lands of Biensten and de Wonner, &c. The reclaiming of the La Chartreuse swamp near Bordeaux is also a classical example. After the work was commenced in the summer of 1805, an appalling epidemic broke out which caused 18,000 cases of pernicious malaria and 3,000 deaths. A similar occurrence also took place in the neighbourhood of Peterborough about 1860, following the reclamation of the Whittlesea mere. In his report to the Privy Council on this outbreak, Dr. Paley remarked, "The first effect of the improved drainage of the large Fen districts has been rather to increase the prevalence of ague." In Bengal, the construction of embankments in the delta tracts has been followed by similar results. But in this case the evil has been infinitely greater. In all the other instances mentioned, reclamation was finally completed, so that the reclaimed areas became rich farm lands, from which the local population eventually derived great benefit. But in Bengal there has been no attempt to turn the rice swamps into wheat land and pasture. On the contrary, natural irrigation with river water has been stopped and drainage obstructed. And the inevitable result has been agricultural deterioration and epidemic malaria. It must not be supposed that those responsible for the embanking of the country had any idea that such results would follow. They aimed at increasing the welfare of the community by preventing floods and improving communications. But the disastrous results of this policy has at last become apparent, and every endeavour must now be made to prevent the continuance of the error and to remedy, as far as possible, the evils that have occurred through past mistakes.

How to Prevent the Extension of Malaria in Bengal.

The Remedy for Malaria in the Delta Tracts of Bengal.—The great increase of malarial disease that has taken place in many deltaic areas in Bengal is inextricably bound up with a coincident decline of agricultural production owing to diminished natural irrigation and impoverishment of the soil. The common origin of these associated evils is to be sought in the decay of the river systems of the delta tracts, accelerated by the embanking of certain main channels, the mischief being further greatly intensified by the construction of thousands of miles of raised roads and railways. At present the natural divisions of Western and Central Bengal are chiefly affected; but certain deltaic tracts in Northern Bengal have long been suffering in a similar manner; and vast areas in Eastern Bengal that have so far remained comparatively immune both from malaria and from the agricultural decline that invariably accompanies an increase of the disease in rural areas, are now seriously endangered owing to the rapid extension of embanked communications of all kinds. At the present moment, therefore, Bengal is faced with two problems: (1) how to avert the threatened extension of malaria, especially in Eastern Bengal; and (2) how best to remedy the malaria already existing both in that and in the other natural divisions of the province.

How to Avert the Extension of Malaria in Healthy Deltaic areas.—Deltaic areas that are as yet free of malaria are characterized by possessing rivers that are still active, spilling over their banks in the flood season and distributing their water through the numerous channels which intersect the country. As a result of the free supply of flood water, these areas are subject to inundation, but as they have few embankments, the water passes freely over the surface of the country doing no harm and bringing wondrous fertility to the soil. At the end of the wet season, the river levels fall and the flood water flows away from the surface of the land leaving the soil well-drained and healthy, alike for crops and for human beings. It must always be remembered that these favoured localities, although they now enjoy a wonderful immunity from malaria, do so only because of the superabundance of surface water that covers the country during the wet season. Moreover, they are in a state of unstable equilibrium. For if conditions in respect to the flow of surface water over the country are interfered with so as to diminish the normal amount of flush and permit instead of the formation of small pools of relatively stagnant rain water so favourable to the breeding of anopheles mosquitoes, these healthy, prosperous districts are capable of becoming intensely malarious. To prevent deltaic areas of this kind becoming malarious, the integrity of the rivers and smaller water-channels must be maintained, their respective spill areas preserved, and normal inundation encouraged. Above all, the erection of embankments of any kind, whether for railway or road communications or other purposes, must be absolutely pro-

hibited until such time as it is possible to devise a method of construction that will not interfere with the natural irrigation or the drainage of the country, and will neither damage agriculture nor the health of the community. The consequences of embanking deltaic areas are so exceedingly serious, both to cultivation and the public health, that once the danger has been recognized, the obvious course to follow, if these consequences are to be averted, is to stop the further construction of embankments. But action in this direction must be combined with a number of other measures if it is to do more than postpone for a short period the threatened evils of malaria and agricultural decadence. It will be necessary, for example, to examine the rivers and other water-channels with a view of adapting them, if possible, both for irrigation and for purposes of communication. In the latter connection it must be remembered that it is often the urgent demand for improved communications that has led in the past to the heedless embanking of the country, a process fraught with results disastrous alike to health and agriculture.

The systematic examination of the rivers and water-courses in every district must be further supplemented by a survey of their local spill area and the lines of interior drainage. All embankments that already exist must also be carefully scrutinized with a view to determining what effect they have upon the natural irrigation and drainage of the locality and whether the water-ways provided are sufficient for this double purpose. Lastly, the movements of the ground water must be watched in order to determine the level of the local water-table and its seasonal variations, and to discover what influence these fluctuations have upon the growth of crops and the condition of the public health.

Summary of Measures required in Relatively Healthy Deltaic Areas.—Briefly summarized the measures that must be adopted to avert the spread of malaria in all districts possessed of healthy deltaic or sub-deltaic areas are as follows:—

(1) Prohibition of further embankments. (2) Survey of existing embankments and their water-ways. (3) Survey of river channels and other water-courses. (4) The mapping out of local spill areas and lines of drainage. (5) Improvement of existing water-channels. (6) Examination of the local water-table.

In addition to the measures enumerated above, an attempt must also be made to determine, as accurately as possible, the existing conditions in respect both to malaria and agriculture. Much of the work thus briefly outlined can be undertaken immediately by the existing staffs of engineers, overseers and sub-overseers and the health officers employed by district boards. Such further assistance as may be necessary should be provided by Government under the direction of the respective departments of irrigation, agriculture and public health.

Malaria Survey of Relative Non-Malarious Districts.—In order to map out roughly the relatively healthy deltaic areas in any district and differentiate them from those that are already seriously affected with malaria, a complete malaria survey is not absolutely essential. Valuable information can be obtained without great difficulty by a study of the census reports, the vital statistics and the returns of cases of sickness admitted for treatment at the various dispensaries; and this can be supplemented with estimations of the splenic index in various localities. The census returns show the relative increase of population in thana areas. For our present purpose, areas in which the increase of population has approximated to 10 per cent. in the last decade may be considered "healthy" without further investigation. If the increase has been less than this the birth-rate, death-rate and fever death-rate for the past ten years must be examined. If there is only a small excess of births over deaths and the fever death-rate has shown a tendency to rise, the fever index of the area must be examined, provided there is a local dispensary or dispensaries from which data for this purpose can be obtained. The "fever index," as defined by Sir Ronald Ross, is the ratio of fever cases to the total admissions for all kinds of sickness. The number of new admissions only, both of fever and of total admissions, is taken into consideration for the purpose of preparing the "fever index."

Every district possesses a number of dispensaries. By calculating the fever indices of each of these dispensaries, a rapid estimate can be made of the relative amount of malaria in the various localities they serve. When the figures from each dispensary have been obtained, they may be noted on a map. Maps must be prepared of each district showing (1) the increase of population in the thana areas, (2) the excess of births over deaths, (3) the relative fever death-rates, and (4) the fever indices obtained from the dispensary figures. The information obtained in this way must be further supplemented by obtaining the spleen indices of groups of villages at different points throughout the district. The spleen index is obtained by examining a number of children between the ages of two and ten years, recording the numbers examined and those showing definite enlargement of the spleen on palpation of the abdomen. The ratio of the latter to the total number of children examined is the "*spleen index.*" Besides noting actual cases of splenic enlargement it is usual to record the approximate amount of the enlargement present by measuring it roughly in fingers' breadths below the costal margin. Children might be examined with advantage in villages at various points all along the various lines of communication in a district and also along the banks of the larger streams and the results indicated on a map. When the information detailed above has been obtained and the five sets of maps have been drawn up, it will be possible to correlate the data regarding malaria with that obtained by the survey of embankments, water-courses, spill areas and drainage. An indication will thus be obtained of the areas in which preventive work is most necessary.

Colonial Medical Reports.—No. 186.—Bengal (*contd.*).

The Amelioration of Malaria in the Deltaic Tracts of Bengal.

"*Malaria cannot be successfully combated merely by the distribution of quinine and the supply of mosquito nets.* The Government of a country devastated by the disease must conduct its campaign against the enemy under the generalship of the engineer and the agriculturist, rather than of the sanitary commissioner and the medical scientist. To the latter all credit is due and has in Italy been accorded for the discovery first made in that country of the true cause of malarial fevers[1]. But the expulsion of the pestiferous insect from the land requires the whole machinery of the State and the co-operation of the entire population to be brought into action."—*Sir Edward Buck, K.C.S.I., LL.D.*

The Nature of the Problem.—The earlier chapters of this report have shown that the prevalence of malaria in vast tracts of Western and Central Bengal and smaller areas in both Northern and Eastern Bengal is inextricably bound up with agricultural decline, impoverishment and depopulation. Malaria is a specific infectious disease that, under favourable conditions, can be eradicated by suitable measures aimed at destroying the parasite or the anopheles mosquitoes which transmit it. Physicians know that an acute malarial infection occurring in a person who is favourably situated as regards food, clothing and housing and who can afford to adopt the proper measures, will usually yield to specific treatment very quickly. It is otherwise with the sufferer from chronic malaria, exposed for a long period to semi-starvation and adverse circumstances of all kinds. In his case specific treatment will fail to achieve its purpose, unless it can be combined with generous diet and other measures for improving his general health and relieving his miserable condition. What holds good with individuals holds good also in the case of communities. The amelioration of malaria in the progressive portions of Bengal, where agriculture is flourishing and prosperity increasing, is a relatively simple problem. In these favoured areas much may be hoped from specific anti-malarial sanitation, whether aimed at destroying the parasite with quinine or the anopheles mosquito; and the results of such measures may be expected to be directly proportionate to the expenditure incurred. But neither quinine nor anti-mosquito measures will restore declining agriculture, prevent the impoverishment of the people, or check depopulation, conditions that are characteristic of the decadent, malaria-stricken deltaic tracts in many parts of Bengal. In their case a much more fundamental remedy is required. And unless this remedy can be applied, there is little hope of reclaiming them from their present miserable condition.

Fortunately, a remedy is available; a remedy which promises to relieve the country from economic stress and the Government from financial embarrassment; a remedy that in the past has been adopted with complete success in many deltaic areas once threatened with absolute ruin by agricultural decline, impoverishment and depopulation. And this remedy can be applied in the case of Bengal also with the certainty of equal, if not greater, success. This remedy, moreover, will also eventually provide the resources required for applying the more specific measures of anti-malarial sanitation on a scale adequate for the control and final eradication of malaria. This great remedy referred to is bonification. And the particular method of bonification peculiarly adapted for application to decadent deltaic tracts is irrigation. The whole question of bonification is so important that an entire chapter will be devoted to its discussion; meanwhile, the specific measures of anti-malarial sanitation must be considered in detail. Financial considerations at the moment stand in the way, so that these measures cannot be applied at present on a scale commensurate with the evil they are designed to remedy; nevertheless, they must be given their place in the plan of campaign; and, when economic conditions have been restored by irrigation, it is to these measures that we must eventually look for the final triumph over malaria. Specific anti-malarial sanitation is in the nature of a direct offensive. A direct offensive against a strongly-entrenched enemy is extremely costly and may fail, unless pushed home with the greatest vigour regardless of expense. A skilful general whose immediate resources are limited, instead therefore of courting failure and loss by attempting a frontal attack that must end in failure, strives to keep the enemy at bay while seeking to make their position untenable by a threat to their flank or rear or a bold stroke at their communications. But let the enemy once relax his hold and our good general will drive home his attack all along the line. The same course must be followed in the campaign against malaria. Malaria, the arch-enemy of Bengal, is at present so strongly entrenched in many parts of the country as to defy direct attack on any scale now possible with the meagre resources at our disposal. But malaria can be forced to evacuate its strong position by a flank attack directed upon its main allies, agricultural decline, economic stress and depopulation. This flank attack must take the form of irrigation; and as the methods of irrigation specially adapted for application in the delta tracts of Bengal will also reduce the number of dangerous anopheles mosquitoes very greatly, irrigation will thus strike a simultaneous blow at the transport or line of communications of the malaria parasite. When, as the result of irrigation, agricultural prosperity is restored, the food supply of the people increased, depopulation checked and anophelines simultaneously reduced in number, malaria will suffer its first defeat and gradually begin to retire. Every possible measure of direct attack must then be concentrated upon it with the object of hastening its final discomfiture and driving it completely out of the country.

[1] The discovery of the malaria parasite was made by Laveran in Algeria, and that of the mosquito cycle of the parasite by Ross in India.

Direct Attacks upon Malaria.—Direct attacks can be made against malaria by the following measures:—

(1) Medical treatment aimed at destroying the malarial parasite by the use of quinine.

(2) Anti-mosquito measures specially directed against anopheles mosquitoes and including: (*a*) measures for destroying the adult insect; (*b*) measures for destroying the larvæ (*i*) by the treatment of collections of water with larvicides, (*ii*) by the introduction of small fish and other natural enemies; (*c*) measures for the more effective permanent obliteration of breeding places either (*i*) by draining them, (*ii*) by filling them up; (*d*) measures for the temporary obliteration of the more dangerous small collections of water by "covering" them with an excess of water during the wet season (which is the dangerous period of the year), and thus preventing a large increase of anopheles and spread of malaria that would otherwise occur.

(3) Measures of protection aimed at preventing anopheles from biting human beings by the use of mosquito nets, protective clothing and medicaments which tend to repel adult mosquitoes, and the application to the windows and doors of dwellings of wire-gauze screens.

Combating Malaria by Quinine: the Italian System.—Experience has shown that malaria can be greatly diminished by the widespread use of quinine. In many countries therefore attempts have been made to encourage the use of quinine by making it easily available to the population at a relatively low price. This method has been already used to some extent in India; but it has been much better organized in Italy and Greece. Similar measures have been adopted in Portugal, Austria, Russia, Algeria, Corsica, Bulgaria and Argentina. In most of these countries, the measures adopted by the Government for the popularization of quinine have been greatly assisted by voluntary philanthropic associations, such as the Anti-Malarial League of Greece and the Italian Red Cross Society. Following the earlier example of Bengal, the Italian Government at first aimed at providing a supply of quinine throughout the country and making it available to all classes of the community at a fixed price. They did not, however, make it a State monopoly or interfere in any way with its supply by private wholesale and retail agencies. The price, while fixed sufficiently low to bring it within the reach of most of the population, was not so low as to prevent chemists and druggists deriving a small profit from the sale of the drug. In order to avoid the charge that they were taxing the infirmities of the people to increase revenue, the Italian Government established the principle that all profits accruing from the sale of State quinine should be devoted to anti-malarial work.

The Supply of Quinine—With the exception of Madras, Bengal is the only province where there has been any serious attempt to maintain a stock of quinine sufficient to meet the local demands. Not only has Bengal manufactured her own quinine, but she has bought larger amounts than any other province. It is probable that, provided she can procure cinchona bark for manufacturing purposes, she could allow for a great local expansion in the use of the drug. Last year the sale of quinine through postmasters nearly reached 9,000 lb., and it is possible the total consumption of Government quinine in the province, including that given gratuitously, and that purchased direct by dispensaries, &c., may have been about 17,000 lb. If the Bengal Government had to consider only their own wants they could, with the present manufacturing facilities, meet a demand three times as great as the present one, provided only that cinchona bark can be made available. The bark on the trees at the cinchona plantations is limited, equalling about 150,000 lb. of quinine. But by purchasing the bark Bengal can always manufacture quinine at a cost much below that of the current wholesale price of the drug, viz., under Rs. 10 per lb., as against Rs. 40 to Rs. 50. It would cost, for example, at present rates Rs. 20 to Rs. 25 lakhs to purchase 50,000 lb. of quinine, which could be manufactured if bark is available at a reasonable price for less than Rs. 5 lakhs.

Gratuitous Distribution of Quinine.—Turning to the question of gratuitous distribution of quinine, it must be pointed out that the charitable dispensaries throughout the province provide an agency through which a considerable amount of quinine is every year distributed to the necessitous poor. Reference to the annual reports on the working of hospitals and dispensaries shows that a very large number of patients receive treatment for malaria at these institutions. The total number of admissions for malaria reported in 1923 is 2,135,934.

Fever Cases attending Dispensaries in 1920.—During 1920, the admissions for malaria at 561, out of total of about 700, dispensaries in the province numbered 1,811,739.

Compared with figures obtained in a somewhat similar manner in 1912 and 1917, there appears to have been a great increase of malaria in the last four years. In Eastern Bengal, the fever index is now much higher than in 1912. As the people in Eastern Bengal are generally speaking much better off than those in Western and Central Bengal, they can afford to purchase quinine, hence the larger sales in the former division. The largest number of malaria cases attending individual dispensaries is met with in Central Bengal with an average of 5,505 new admissions per annum; Western Bengal comes second with 4,646; Northern Bengal third with 2,925; and Eastern Bengal last with 1,648.

The Infected Population.—The population infected with malaria is enormous. At the 1911 census, the total population of the province was 45,483,077.

At a rough estimate some thirty millions of these people are infected with malaria and more than ten millions suffer from the disease in an aggravated form. Only a very small proportion of the thirty million cases of malarial infection in the province receive treatment sufficient to afford them relief. A few thousands only get really adequate treatment

in the larger hospitals and dispensaries; under two million receive treatment which is wholly inadequate as far as the supply of quinine is concerned at some hundreds of smaller dispensaries throughout the province; possibly 100,000 or so are attended by qualified medical practitioners; but the vast majority of the sufferers from malaria receive either no medical attention whatsoever or are entirely dependent on such services as can be obtained from untrained village practitioners. A very large number of sufferers from malaria who could afford better treatment rely instead upon one or other of the many quack remedies in the form of fever specifics which are widely advertised in nearly every newspaper as sure cures for malaria. These people usually enjoy the doubtful advantage of purchasing more or less ordinary quinine mixtures under fancy names at a price often ten times their actual value. In recent years the manufacture of spurious quinine tablets bearing a superficial resemblance to those prepared and sold by Government has come into prominence. Bakarganj district has sprung into notoriety in this connection because of the number of manufactories of these bogus quinine tablets which have been discovered there and which have been sending out supplies of the spurious tablets to agents for sale in many other parts of the province.

Value of Quinine and Need of Improving the Supply.—From what has been stated, it will be apparent that the eradication of malaria from Bengal by the use of quinine is at present a proposition that is absolutely impracticable. But it must on no account be forgotten that quinine and the other cinchona derivatives are the most valuable medicinal remedies for malaria that the world has yet seen. A cheap and abundant supply of quinine and other cinchona alkaloids is therefore a necessity. Moreover, the Government of any malarious country that can secure such a supply and ensure that each individual in the population learns both the value of the drug and how best to employ it in case of necessity, confers an inestimable blessing upon its people.

Bengal must therefore face the problem of quinine supply. Much could be said in favour of increasing the manufacture of quinine and cinchona febrifuge. In view of the market price, it would pay to do this even if cinchona bark cannot be imported, for there are possibilities of further extending the plantations because cinchona *succirubra*, which yields the red bark, can be grown at relatively low elevations, some authorities giving 1,500 feet as the lowest limit. The red bark, although not so rich in quinine, yields a large supply of the other cinchona alkaloids which are equally as good as quinine, if not more efficacious in the treatment of malaria. *Cinchona succirubra*, besides growing at a much lower elevation than *Cinchona officinalis* and *Cinchona ledgeriana*, is also said to mature much more rapidly, viz., in five years, as against nine years. It is supposed that very little land is available for planting cinchona at the higher elevations required by *C. officinalis* and *ledgeriana*. It is possible, however, that a considerable area might be found capable of being planted out with *C. succirubra*. Inquiry might show also that the latter would grow in Chittagong hill tracts. Both these possibilities are worth investigating.

Combating Malaria by Anti-Mosquito Measures. The Area to be dealt with.—We have now to consider the possibility of reducing malaria by specific measures of mosquito control. Some idea of the stupendous nature of the task may be gathered from an estimate of the area that would have to be covered by these measures in order to bring about the desired results. The total number of villages in Bengal, as shown by the census of 1911, was 119,334, distributed as follows:—

	Villages	Houses	Population	Average houses	Average population
Western Bengal	24,104	1,858,879	8,467,314	78	350
Central ,,	13,341	1,703,921	9,445,321	125	633
Northern ,,	30,081	1,869,633	10,138,302	47	259
Eastern ,,	43,106	3,199,069	17,432,140	74	404

These figures are only approximate. In the case of the Presidency Division, 1,000,000 has to be deducted from the total population to exclude greater Calcutta and allow for obtaining the average village population.

An approximate estimate of the probable number of villages in which anti-malaria measures would be required may be obtained by using the fever indices of dispensaries in the different divisions. Each dispensary serves a number of villages in its vicinity, and the fever index gives therefore some indication of the amount of malaria in these villages. Excluding areas in which the fever index of 1920 was under 20 per cent., we may say that measures would be required in at least 80,000 villages. Moreover, conditions are very bad indeed in a large proportion of these villages where the fever index is probably over 50 per cent.

We have to consider the possible treatment of practically 70 per cent. of the total villages in the province, over 30 per cent. of which are very severely affected with malaria.

The various types of anti-mosquito work must now be discussed in detail.

Destruction of Adult Mosquitoes.—Mosquitoes may be destroyed by fumigation, or they may be caught in traps or in a hand net and afterwards killed. Fumigation has long been employed in Italy and the United States. The burning of resin is often resorted to in Indian houses in order to drive away mosquitoes. Unfortunately, it does not kill them. Although the destruction of adult stegomyia mosquitoes was of some service in campaigns against yellow fever, Gorgas himself admits that too much reliance was at first placed upon this measure at Panama, and more effective measures aimed at the larvæ did not receive enough attention until experience showed that fumigation by itself was ineffective in checking the disease. The destruction of adult mosquitoes is even less useful

in preventing the spread of malaria. "Hence," says Ross, "the expensive and troublesome process of fumigation is not much employed in malaria prophylaxis." At Panama, mosquito traps and the capture of mosquitoes by hand were used as subsidiary measures in the campaign against malaria. Traps are really of little value except for the capture of mosquitoes for the purposes of a survey or for laboratory work. The capture or destruction of mosquitoes by hand is also of minor importance and in the absence of other measures cannot make an appreciable difference to the spread of malaria.

Ross suggests that the offer of rewards of a penny (an anna) for fifty anopheles may quite possibly lead to a large slaughter by village children. It may also have a contrary effect. On one occasion a planter offered a small monetary reward for the capture of anopheles only to discover after some time that one of the cleverer boys had learned how to breed large numbers in order to make money easily. Bats, birds, lizards, toads, dragon flies and certain other flies are known to catch mosquitoes. Bats have even been encouraged for this purpose in certain parts of California. But although these animals may reduce mosquitoes to some extent, no one can seriously suppose that they could be used as the main instrument for the control of malaria in Bengal.

Measures for Destroying Anopheles Larvæ: Larvicides.—Sir Ronald Ross was the first to propose the control of malaria by the destruction of anopheles larvæ; and the methods suggested by him have been used with marked success at Ismailia, Panama, Havana and many other places. The treatment of collections of water with kerosene or crude petroleum is the simplest method and is now familiar to all. Other preparations may be used also, including emulsions of crude creosote, coal-tar disinfectants and solutions of certain chemicals; but these are generally more expensive than the oil. The cheapest campaign against mosquitoes by oiling was carried out some years since at Port Said, a place where there is little rainfall. The work cost about fivepence (five annas) per head of the population, which is a very low figure, impossible now that prices are so high. Even five annas per head of the population would amount to a very large sum in Bengal. In Calcutta alone, it would mean over three lakhs per annum, and in Bengal it would amount to nearly one and a half crores of rupees per annum. But this latter sum would not be anything like sufficient for the control of the dangerous anopheles mosquitoes in the province.

Destruction of Anopheles Larva by Small Fish, &c.—From time to time the suggestion is made that malaria can be controlled by introducing small fish, ducks or other natural enemies of mosquito larvæ into the collections of water in which these larvæ breed. "No cheaper and better anti-malarial measure," says Ross, "than the extermination of anophelines by natural enemies could be conceived or devised—were such a thing possible." "Unfortunately," he adds, "experience proves that animals and plants survive, even in large numbers, the introduction of their most deadly enemies; they succeed in finding some refuge or other, and a state of commensalism is finally arrived at." He cites Panama as an example where anophelines abounded in spite of the presence of hosts of fish which preyed upon them, and he also states that he "saw a ditch in Calcutta full of small fish and absolutely thick with mosquito larvæ; and have observed fish and larvæ living together in rice fields."

A considerable amount of study has been given to the mosquito-destroying fish of Bengal by Dr. Chaudhuri and others. Observations also have shown that these fishes are widely distributed both in the most malarious and less malarious areas. There are grounds for believing that the supply of fish generally has greatly diminished in many areas in Bengal. The reports of Sir Krishna Gupta and Mr. K. C. De, C.I.E., I.C.S., are both unanimous upon this point; one of the causes being the gradual drying up of the streams and swamps and a general reduction of surface water, and if this is so, the mere introduction of fish without a corresponding increase of water in which they could live would not be likely to prove effective. As it is, almost every collection of water containing anopheles larvæ also contains one or other species of fish that preys upon them. It is only those ignorant of this fact who usually make the suggestion that malaria can be diminished by the introduction of fish.

Irrigation, it may be observed, would undoubtedly favour the increase of fish, and thus help to reduce the number of anopheles. In this connection, the following quotation from a paper read by General Schangti-tong at the Paris International Congress of 1889 is not without interest:—

"I may add that without these gigantic irrigation works, the Chinese could never have carried to such a pitch of perfection one of their most important industries. I speak of pisciculture. Thanks to the abundance of water, the whole of my countrymen, instead of contenting themselves with covering with their fishing boats the seas, rivers and lakes of our country, have devoted themselves to the breeding of fish. The spawn is everywhere carefully collected; far from leaving it to take its chance, the peasant gives this source of wealth a safer shelter in some spot where a perennial supply of water can be assured. The irrigation reservoirs teem with fish. During winter the rice fields are fallow; the water is led into them, and they are instantly full of carp. This industry allows us to make fish a considerable factor in the food of our people. The fish are either eaten fresh, or salted, and dried; they are despatched to all parts of the Empire and sold at a price which is remunerative, though it is exceedingly cheap."

Obviously under the conditions depicted in the above passage, anopheles larvæ can have but little chance to multiply; and it is possible that intensive pisciculture is one of the causes of the remarkable immunity from malaria enjoyed by the deltaic tracts of China.

Colonial Medical Reports.—No. 186.—Bengal *(contd.)*.

Control of Anopheles Breeding Places by Draining or Filling.—Where feasible the control of anopheles breeding places by drainage or their permanent obliteration by filling them up with earth is always advisable. But a consideration of the facts shows that we cannot look to either of these measures for the control of malaria on a large scale in the deltaic areas of Bengal. The vast majority of the infected villages are situated in the deltaic portions of each division where, in the flood season, the level of the rivers is so high that drainage by gravity is out of the question. Drainage by pumping is utterly impossible, not only because of the cost, but owing to the fact that drying the land surface to a degree sufficient to prevent malaria would also prevent the cultivation of rice on which the population depends for its food supply. The village sites in the deltaic areas in which malaria is specially intense are riddled with ditches and borrow-pits of all kinds, and the filling up of the excavations in 80,000 villages is an absolutely impossible task. It is stated that some years ago a rough estimate was made of the cost of filling up borrow-pits, in the municipal areas only, of another province. It is reported that this estimate amounted to two years' total revenue of the province in question.

In recent years certain experiments have been carried out to determine the feasibility of reducing malaria in the more undulating country that exists in the extreme west and the north of the province. In the one case, at Singaran-Toposi, the scheme of work included the periodic flushing of the local river by means of a sluice, the filling up of numerous hollows and depressions and the drainage of many small swamps and other collections of water. By these means a considerable reduction has been effected in the number of anopheles. And on general report there has been a corresponding diminution in the amount of malaria. But the disease has not been nearly eradicated as yet and, although the country dealt with covers considerably over one square mile, it now seems probable that this area is too small to allow the measures a chance of complete success. Similar conclusions have been arrived at in the case of Minglas, where under-draining has been chiefly resorted to and where, within an area covering 500 acres, anopheles breeding places have been almost entirely abolished by this method of draining. Here also the measure of success achieved at present is not sufficient to warrant the assumption that in places such as this, where the infection rate is very high, the total obliteration of anopheles breeding places over an area less than two square miles will serve to eradicate malaria. As the cost of measures of this kind is heavy and increases in proportion with the size of the area to be dealt with, it is clear that at present we cannot count upon eradicating malaria from Bengal by means of drainage and the filling up of hollows.

The Temporary Obliteration of Anopheles Breeding Places by Flooding or "Covering" with Water.—"Covering with water" is Nature's method for controlling malaria in low-lying deltaic swamps. Every year this measure can be seen in action with the happiest results in vast areas in Eastern Bengal. Again and again in past years also the good effect on malaria of high floods in the rivers and copious inundations have been put on record by a host of medical men and other observers. Recently an attempt has been made to apply this method in the case of certain small areas in Bengal that have long been malarious. To this end a small scheme has been carried out at Jangipur and another of a rather different character in a portion of the Burdwan district. The effect of the work at Jangipur is spoken of favourably by the local residents. In 1918, the headmaster of the high school stated that "the health of the town of Jangipur was good when all the surrounding villages as well as all places in this division were subject to the widespread ravages of influenza and malaria. But since the introduction of the anti-malarial scheme, the health of the town has considerably improved." In the same year the superintending engineer in charge of the Banka Valley Scheme reported that:—

"The regulator was used for regulating the depth of water on the land, with the result that the crops, which otherwise would have been destroyed by heavy rain and floods in the Banka, have been saved."

Prevention of Malaria by Protection from the Bites of Mosquitoes.—Protection from mosquito bites can be secured by the use of mosquito nets, screening, fans and repellent oils and medicaments. The educated and well-to-do classes may protect themselves from malaria in this way to a great extent, but the poor will generally refuse the expense incurred. The cost of a good mosquito net is beyond the reach of a vast majority of the people, and the cheap nets now used by some of them soon wear out. The cost of screening a house is very heavy. Punkhas and fans are not practicable for the mass of the population and medicinal culicifuges are of little real value. The dwellings of the poorer classes are everywhere permeable to mosquitoes and to protect such houses would cost as much as rebuilding the whole house. While therefore protection should be urged upon everyone as strongly as possible, this measure cannot be considered as likely to prove immediately effective in reducing the malaria of the community as a whole to any great extent.

In Bengal, although the number of houses is stated to be about one for every five of the population, each house in the rural area consists of a number of isolated huts. The cost of screening these huts, or even providing a mosquito net for each of the inmates, would mount up to a very large sum. To provide the cheapest form of net for the 30,000,000 people in the 83,000 malarious villages would cost at least ten crores of rupees, and at the end of a year most of the nets would be useless. Obviously, therefore, protection from mosquitoes cannot be looked upon as a practicable measure of general malaria control for Bengal at the present time.

Co-operative Anti-malarial Societies.—Although financial considerations at present preclude the extended use of the majority of the specific anti-malarial measures referred to, it by no means

follows that these measures are to be abandoned as useless. On the contrary, they must be adopted wherever possible as far as means will allow. When a general finds that his available supply of ammunition or his heavy artillery is not sufficient to enable him to defeat the enemy by a frontal attack, he neither discards these weapons as useless nor wastes them in fruitless assaults. On the contrary, he employs them when a suitable opportunity offers or husbands them carefully until such time as his resources can be increased sufficiently to enable him to employ them with a certainty of success. Every one of the anti-malarial measures that we have been discussing has its place in the campaign against malaria, and must be applied whenever it can be used to the best advantage. In this connection, attention must be directed to an interesting movement for the formation of co-operative anti-malarial societies that has recently been initiated by Rai Bahadur Dr. Gopal Chandra Chattarji. The aim of this movement is to establish societies for mutual self-help against malaria; and for achieving this purpose many of the various measures referred to are being made use of as far as means will allow. This movement is full of promise. For, quite apart from the immediate results attained against malaria, it offers a valuable means of educating the public and gradually enlisting their help against the common enemy. The movement is at present in its infancy, but it merits every encouragement, for it appears destined to become an important agency for the final eradication of malaria from the country. The fact that societies of this kind are in existence and are making an attempt to improve the localities in which they have been established is a most hopeful sign. And if the originator of the movement lives to see societies of this kind established in every village union throughout the province, he will have achieved his purpose and provided a most potent weapon by which the final control of malaria may be accomplished. Every endeavour should, therefore, be made to further the establishment of co-operative anti-malarial societies throughout the province.

The Effect of Godavari Irrigation on Malaria.—Since the completion of the great irrigation project in the delta of the Godavari, malaria has greatly declined and has now become almost a thing of the past. And the same result has been achieved in the neighbouring delta of the Kistna, where a similar irrigation project has been carried to completion with enormous benefit to the people. Europeans and Indians alike bear witness to the extraordinary immunity from malaria now enjoyed by those residing in these two deltas, in spite of the fact that they live surrounded by rice cultivation, which often extends almost up to the doors of the houses. This was not always a characteristic of the Godavari delta. On the contrary, that area once bore an unenviable reputation owing to the prevalence and severity of malaria. While the irrigation works were still in progress malaria epidemics occurred from time to time and attracted considerable attention. This was especially the case between 1869 and 1873. In 1871, a special medical officer was sent to investigate the outbreaks, which in some quarters had been ascribed to the influence of the irrigation works.

It was not long before the beneficial effects of the irrigation works in reducing malaria began to be apparent.

Sir Arthur Cotton, writing of the Godavari delta in 1878, said: "While the delta has very little fever, the moment you go into the upper tracts you encounter it continually." The improvement in the public health conditions, as regards malaria, has steadily continued. And now, as we have seen, malaria is practically a thing of the past. The *Gazetteer* of the Godavari district contains a statement in this connection, which re-echoes the views of Sir Arthur Cotton. "The fact remains," it says, "that the delta taluks (unlike irrigated areas in some places in this Presidency, the valley of the Tungabhadra, for example) are not greatly subject to malaria, and are, in fact, the part of the district in which it is least prevalent." There is statistical evidence to prove that this is no fancy picture of the conditions relating to malaria. Reference to the annual report of the Dispensaries of the Madras Presidency for 1918 shows that among a total of 449,615 out-patients admitted for treatment at dispensaries in the Godavari delta, only 24,954, or 5·5 per cent., were suffering from malaria. This is in striking contrast to the records of fifty years ago when, as we have seen, malaria was so prevalent in the delta as to be made the subject of a special Resolution of Government.

Reference has been made to the Kistna delta which adjoins that of the Godavari, and like it enjoys the benefits of irrigation. And as in the Godavari delta so also in that of the Kistna, among the blessings bestowed by irrigation, immunity from serious malaria is not the least. At the Simla Malaria Conference of 1909, the Hon. Mr. Weir, I.C.S., drew attention to the fact that the Kistna delta was free of malaria in spite of extensive rice cultivation.

How Bonification Influences Malaria.—Bonification causes a reduction of malaria by the interaction of the following factors:—

(1) Reduction in the numbers of the local anopheline carriers of malaria.

(2) Increase in the number of the local human population.

(3) Increase in the prosperity of the local human population.

At the moment it is unnecessary to discuss the relative importance of these three factors, and it is doubtful if the data available is sufficient to enable us to come to a decision on this point. All that need be stated for our present purpose is that there are grounds for believing that each of the three factors named exerts a favourable influence upon malaria; and that, when these favourable influences are all acting together, the cumulative effect upon malaria is so great as to cause a very marked reduction in the prevalence of the disease

Effect of Reduction of Anopheles on Malaria Prevalence.—It is now universally admitted that a reduction in the number of anopheline carriers of malaria reduces the spread of malarial infection. Ross has pointed out that a complete reduction of anopheles is not essential to the eradication of malaria. "Malaria," he says, "may be completely reduced even by a partial reduction of the anophelines below the necessary limit (which I have roughly estimated to be about 40 different anophelines per head per month) and it may be partially reduced even by a smaller reduction of the insects."

Let us try and get a clearer idea of what this proposition may actually mean in practice. Accepting certain of Ross's mathematical assumptions for this purpose, let us assume that we have to deal with a square mile of malarious country inhabited by 1,000 people, both the human and anopheline population being evenly distributed throughout the area. What would be the effect of permanently reducing the number, or in other words the relative density, of the anopheles mosquitoes? The reduction might conceivably be effected either by obliterating the breeding places or by keeping a permanent staff at work destroying their larvæ, as was done in Panama. Suppose the initial infection rate is very high, so that 999 out of the 1,000 people are infected with malaria. In this case, even very thorough anti-mosquito measures will fail to effect an appreciable reduction in the number of malaria infections.

Now, while it is often an easy matter to reduce anopheles by 25 per cent., and not very difficult to diminish them by 50 per cent., a 75 per cent. reduction is not so easily effected, and to reduce them by 90 per cent. means very careful and thorough work indeed. But even a 90 per cent. reduction of anopheles would not necessarily produce any appreciable effect upon the prevalence of malaria in severely infected areas. The term "appreciable" is used advisably, because existing methods of measuring the malarial infection rates of a community are at present inadequate for clearly demonstrating such small differences in actual infection rates as those between 99·9 and 99 per cent., or even between 99 per cent. and 90 per cent. But there is another reason why even a 90 per cent. reduction of the anopheles breeding within one square mile cannot possibly produce much effect upon malaria, if the initial amount of infection is very great; and this is the effect of migration of anopheles from outside the treated area. In regions of intense malaria, it is not enough merely to abolish all breeding places within a square mile if we wish to protect the people dwelling within that area.

Even if we abolished all anopheles breeding places within our one square mile, migration from without would still supply enough anopheles to keep the rate of infection at over 99 per cent. a quarter of a mile from the boundary and 95 per cent. at the exact centre in the one case, and 91 per cent. at a quarter of a mile from the boundary and 60 per cent. at the centre in the other. In the circumstances stated, therefore, although very thorough and expensive measures may be adopted, they may appear in practice to be absolute failures. And this explains why quite a number of schemes in very malarious parts of India have been looked upon as failures. Now let us glance for a moment at the other side of the picture. Suppose that, instead of 999 or 990 infected persons among the 1,000 in our square mile, only 500 are infected at the beginning, what will be the final result of anti-mosquito measures producing similar reductions, viz., 25 per cent., 50 per cent., 75 per cent. and 90 per cent., in the proportions of anopheline mosquitoes present?

A very substantial fall in the number of malarial infections would follow a relatively small reduction of anopheles mosquitoes, viz., 25 per cent., and the disease would tend to die out completely if the anopheles mosquitoes are reduced by only one-half. When the initial rate of infection among our 1,000 people is lower than 50 per cent., the results would be even more successful and dramatic.

These conceptions are very interesting and also very important, both when considering the application of anti-malarial measures in practice and for understanding the manner in which bonification can bring about a reduction of malaria. In the first case, they enable us to grasp the fact that anti-mosquito measures have their limitation; that in certain places they can be applied with the certainty of producing excellent results, whereas in other circumstances they may appear practically useless; and in the second case they help to explain how irrigation and other measures of bonification that, although primarily aimed at improving agriculture, may also reduce the breeding of anopheles to a considerable extent, will be able to produce a great diminution of malaria.

Some Economic Aspects of Bengal Malaria.—Attention has already been called to the fact that a serious decline of population indicates that a definite change has come over the affected area; and the effects of such a change are not limited to man, but are certain to exert a very marked influence also on both the flora and fauna of the locality, resulting in an increase of certain species and a decrease of others. This view is borne out by the evidence which shows that both the plant and animal life of the areas undergoing depopulation exhibit an increase in certain directions and a decrease in others, and many of these increases and decreases are of special importance to man from an economic standpoint, affecting as they do the question of available food supply very greatly.

The most prominent and best recognized change in relation to fauna is to be seen in the great increase of malaria. If we compare a map of the areas suffering from a decline of population with another showing the relative prevalence of malaria we shall see that there is a rough correspondence between them. Depopulation is, therefore, generally associated with intense malaria. Evidence points to the fact that in the areas in which the human

population is declining malaria has increased very greatly during the last sixty years.

Burdwan, Birbhum, Bankura, Midnapur and Hooghly in Western Bengal were at one time relatively free of malaria and were regarded as sanataria. Similarly Murshidabad and Nadia and a great portion of Jessore in Central Bengal were formerly healthy, and Pabna and Malda in North Bengal were also relatively salubrious. In Eastern Bengal, Tangail in Mymensingh, Manikganj in Dacca, and the northern portions of the Faridpur district, which are now malarious, were formerly relatively free of the disease.

This admitted increase of malaria can only be explained on the assumption that there has been a corresponding increase in the number and distribution of anopheles mosquitoes and malaria parasites in the areas affected. Unfortunately, there are no actual observations on this point. But it must be remembered that the malarial parasite was only discovered in 1880, and the part played by anopheles mosquitoes in its transmission as late as 1898, long after this increase of malaria had taken place. Many healthy localities in which population is increasing usually show scanty signs of malaria. But anopheles mosquitoes of species capable of harbouring the malarial parasite are to be found everywhere and often occur in large numbers in these healthy areas. They do not, however, appear to multiply greatly during the wet season as they do in the unhealthy areas, so that the period of their greatest prevalence does not correspond with that most suitable for the proliferation of malarial parasites. Meanwhile, it may be noted that there are grounds for believing that in the decadent areas anopheles mosquitoes are now far more prevalent during the period of July to October than they used to be, and that his change is associated with a greatly lessened supply of water.

Putting aside for a moment the increase of malaria and the loss of population, it will be seen that the other changes that have been noted as occurring among the fauna and the flora, respectively, of the decadent areas we have been discussing, point to the conclusion that a reduction in the water supply is the origin of the trouble. First of all there is the receding margin of cultivation. This is invariably associated with a lack of water. It is always the drier more elevated lands that go out of cultivation. Then there is the increase of jungle which is largely confined to the relatively high banks of rivers and old village sites, showing that the type of vegetation is one which prefers a dry situation rather than a damp, waterlogged one. The tendency for *Aus* paddy to displace the *Aman* variety is also an indication of diminished moisture. The decreasing supply of fish affords further evidence of a lessened supply of water; and the increase of wild hog and other animals which has followed the increase of jungle points in the same direction. The only fact, therefore, which appears to militate against this view of the situation is the very great increase of malaria which has taken place along with these other changes, and which at first sight appears to preclude the possibility of a diminished supply of water being the cause of the trouble.

But we have only to recall two well-known facts in regard to malaria in order to realize that this difficulty is only an apparent one. Ever since Empedocles flooded the marshes surrounding Selinos in Sicily by a canal constructed for the purpose, and in this way freed the city from malaria, it has been known that swampy low-lying localities cease to be unhealthy when temporarily submerged; and in the old days flooding was often deliberately applied both in Italy and Holland for ameliorating malaria, with most excellent results. But while the flooding of swamps has long been resorted to for checking malaria the partial removal of water from a marshy area has always been regarded as a most dangerous proceeding, calculated to produce a serious intensification of the disease; this belief being justified by the numerous occasions on which the reclamation of swamps has led to severe outbreaks of malaria. Three well-known instances of this kind are the case of the Grande Chartreuse swamp in France, the lowlands of Biensten and de Wonner in Holland and the Whittlesea Mere in England. Such outbreaks were formerly ascribed to miasma given off from the exposed bottom of the marsh. But nowadays the accepted explanation is the great increase of anopheles that takes place when, by partial drying up, a large expanse of water is converted into many small shallow pools.

The Relative Prevalence of Malaria.—The fever indices show that malaria is far more prevalent in Western, Central and Northern Bengal than in Eastern Bengal.

What is the cause of the disparity? Before attempting to answer this question, we must briefly glance at the salient facts relating to the disease. Malaria is caused by a small animal parasite inoculated into the blood of men through the bite of anopheles mosquitoes. These mosquitoes are not naturally infected with malaria, but have first to obtain the parasites by sucking the blood of human beings already infected. Now mosquitoes require water in which to breed; the adult insects cannot exist for many days in a dry atmosphere; and the malaria parasite also requires a certain temperature to enable it to develop in the body of an anopheles mosquito. Before malaria can become prevalent in any locality, or at any given season, therefore, certain conditions must be fulfilled: (*a*) *firstly*, infected human beings must be present; (*b*) *secondly*, suitable collections of surface water for the breeding of anopheles in sufficient numbers must exist; (*c*) *thirdly*, the humidity of the atmosphere must be favourable to the longevity of anopheles, and (*d*) *fourthly*, the temperature of the atmosphere must be high enough to allow the parasite to develop. Although (*a*) and (*b*) often occur at every season of the year, malaria cannot spread unless the conditions (*c*) and (*d*) are satisfied also, which usually occurs only during the wet season

Colonial Medical Reports.—No. 186.—Bengal (*contd.*).

Malaria naturally tends to increase, therefore, during the wet season, and the majority of new infections are as a rule contracted during this period. But owing to the variable incubation period, which may extend to several weeks, and the fact that the sudden onset of colder days and nights tends to determine attacks of fever in those who have become infected and bring out relapses in persons who harbour the parasite, it often happens that the greatest number of actual cases of malarial fever occurs after the end of the rains just at the beginning of the cold season. Thus, it often happens that when cases of malaria are most numerous the conditions actually responsible for the presence of the infection have for the moment passed away with the change of the season. The greatest mortality from malaria is usually met with at a still later period owing to the fact that persons who are chronic cachectics fall victims to malaria in far greater numbers than do those who are suffering from the initial acute attack that usually follows first infection. Malaria, as we have seen, is chiefly propagated during the wet season, as a direct result of the climatic conditions and the great increase of facilities for the breeding of anopheles, which ordinarily occur at this time of the year, owing to the multiplication of collections of surface water. But in certain circumstances an increase of surface water instead of favouring the breeding of anopheles, tends to diminish their number. The nature of collections of water in which anopheles breed, their size, the character of the water and the temperature to which this water is raised by the heat of the sun, all have an important bearing on the multiplication of anopheles. Small collections of water in pools, drains and streams, which possess a large proportion of weedy edge, are most favourable to anopheles larvæ, owing partly to the amount of shelter and food provided and also because the temperature of the water remains relatively low. Large collections of water possess a relatively smaller ratio of dangerous edge to surface and tend to have a higher temperature. Exposure to the sun may render them very unfavourable for mosquito larvæ, while muddy river water appears to be inimical to anopheles larvæ. Now the cultivation of rice is carried on during the rainy season, which coincides with the periods when anopheles mosquitoes ordinarily tend to multiply, and the transmission of malaria infection therefore becomes most active. In the circumstances best suited to the growth of rice in Bengal, it might be thought that the amelioration of malaria was a hopeless undertaking, because it is often assumed that increasing the water must also increase the mosquitoes and the resultant malaria. But, as we have seen, there is a point beyond which an increase of surface water instead of being favourable to anopheles larvæ becomes unfavourable to them, and results in their rapid destruction. This explains the apparent anomaly that those districts which have the highest rainfall and possess the greatest amount of surface water during the cultivating season are the areas where malaria is least prevalent, where agriculture is in a most flourishing condition and where the rural populations have multiplied at a rate far in excess of what might have been thought possible. An ample supply of surface moisture therefore confers a double benefit, improving the yield of the crops and protecting the population from malaria, and these benefits are most conspicuous in the areas liable to inundation with silt-laden river water. Although malaria is chiefly propagated in the wet season, its ravages become most apparent when that season is over. The anopheles have by this time practically finished their season's work, and no attempt to reduce their numbers can therefore have much effect. It follows that when malaria is causing the greatest amount of sickness and mortality the only remedy that can prove immediately useful is the relief of the sufferers by adequate treatment of the disease. If sufficiently intensive to cure the individual and sufficiently extensive to improve the general health of the community the remedial treatment of malaria by quinine may effect a considerable improvement in the conditions of a limited population. But it offers little hope of effecting a permanent amelioration of malaria in a locality, because it leaves conditions relating to the breeding of anopheles (which are those primarily responsible for the existence of the disease) absolutely unaltered. The aim of the sanitarian, therefore, must be to change or control the environment, so that conditions during the season when malaria is actually propagated are made as unsuitable as possible for the breeding of anopheles mosquitoes, while at the same time the human population is benefited directly and indirectly by the measures adopted.

Colonial Medical Reports.—No. 187.—Cairo.

REPORT OF THE MEDICAL OFFICER OF HEALTH, CAIRO CITY, FOR THE YEAR 1922.

VITAL STATISTICS.

(*a*) Population.

The population for Cairo in 1922, as estimated by the Statistical Department, was 777,500, to which, however, should be added 29,590, which represents the population of the area around Helwân that is administered by us for all public health purposes, with the exception of the registration of births and deaths. This makes a total of 807,090, on which all our zymotic charts are based.

(*b*) Births.

The total number of births which occurred in Cairo during 1922 was 41,596, out of which 40,849 were registered as natives and 747 as foreigners. The annual birth-rate was, therefore, 53·5 per thousand of population. This is the highest rate for the last twelve years.

(*c*) Deaths.

The total number of deaths in Cairo during 1922 was 27,350, including 658 deaths of non-residents. Out of this total 26,738 were among natives and 612 foreigners.

(*d*) Infantile Mortality.

The total number of deaths among children under one year during 1922 was 9,954. Out of this total 9,861 were deaths among natives and 93 of foreign parentage.

In addition to these there were 197 deaths of infants coming from outside Cairo and who died in various public institutions.

Infectious Diseases.

The total for all infectious diseases reported during 1922 was 5,135 which includes 395 cases coming from outside Cairo. The total for Cairo proper was 4,740, which is practically the same as last year. Out of this total 2,555, with a mortality of 850, were cases belonging to the eight principal diseases. The remainder include 1,461 cases of influenza, 180 of chicken-pox, 82 of mumps, 4 of Malta fever, 116 of whooping-cough, 21 of tetanus, 3 of encephalitis lethargica. 318 persons bitten by animals underwent anti-rabic treatment.

Regarding the eight principal diseases the total was 529 larger than in 1921 and was due to a large increase of measles.

With the exception of measles the totals of the eight principal diseases are all below the average of the previous eight years.

Smallpox.—The total number of cases notified during the year was 24, which is satisfactory when compared with the previous eight years. There were 10 deaths from this disease, 9 of which were diagnosed after death.

The ages of those who died from this disease ranged from one month to eleven years. All had been vaccinated with the exception of two who were only one month old.

Measles.—The total number of cases recorded in 1922 was 982, being 700 more than in 1921. There were 332 deaths from this disease, of which no less than 322 were diagnosed after death.

Scarlet Fever.—There were 68 cases notified during the year as compared with 66 in 1921, whilst the number of deaths from this disease was 2.

Diphtheria.—The total number of cases recorded in 1922 was 418, as compared with 438 in 1921. The total number of deaths was 146.

Typhoid Fever.—The total number of cases notified during the year was 859, as against 669 in 1921. This compares satisfactorily with the average number recorded during the previous eight years.

Typhus Fever.—The total number of cases recorded during the year was 183, which is the lowest total during the last nine years.

There were 124 deaths.

Relapsing Fever.—There is little to be said about this disease which was quite insignificant this year. Only 13 cases were recorded, with 4 deaths.

Cerebro-spinal Fever.—There were 8 cases of this disease during the year as compared with 14 in 1921 and 28 in 1920. It is, moreover, the lowest total during the last nine years. The number of deaths was 6.

Puerperal Fever.—The total number of deaths from puerperal fever during 1922 was 58, out of which 55 were among natives and 3 among Europeans. There were, however, 27 deaths which occurred within a fortnight of confinement which, if added to the others, would make a total of 85. The causes of these 27 deaths are given as: abortion 3, hæmorrhage 8, difficult labour 2, eclampsia 5, peritonitis 3, nephritis 1, dysentery 1, uræmia 2, enteritis 1, and heart failure 1.

Influenza.—The total number of cases notified during 1922 was 1,461, as against 1,479 in 1921 and 1,587 in 1920. The number of deaths attributed to this disease was 82.

The number of deaths from all respiratory diseases, excluding pulmonary tuberculosis, was 4,621, out of which 1,900 were due to pneumonia, 2,559 to bronchitis, 24 to pleurisy, and 138 to other respiratory diseases.

Of the 1,900 deaths from pneumonia no less than 1,275 were children up to five years of age, 159 from over five to fifteen, 170 from over fifteen to thirty-five and 296 over thirty-five.

Encephalitis lethargica.—There were 3 cases notified during the year, all of whom died.

Case-mortality of Infectious Disease.—For the benefit of readers of this report, who are unfamiliar with the conditions under which work is carried on in this country it would perhaps be as well to say a few words with regard to the figures shown for case mortality, which must appear to be enormous.

The fact is that the notification of infectious disease is very defective. Many doctors are lax in the performance of this legal obligation. In a very great number of cases no doctor is called in during life, the disease being diagnosed only after death. Cases of recovery from the disease unattended by a doctor never come to our knowledge. The degree to which the case-mortality figures are affected by this state of affairs varies according to the nature of the disease. For example, the case-mortality figure for small-pox is probably nearly correct, but that for measles is very much higher than the fact, the reason being that small-pox makes its existence so evident that it cannot well be concealed and notification of cases which eventually recover takes place to a far greater extent than occurs with regard to other diseases, such as measles.

Again, as all foreigners call in a doctor to attend their sick, those diseases to which foreigners appear to be more susceptible than natives—such as scarlet fever—are likely to be better notified. The case-mortality figures for such diseases will therefore be less widely in error.

Colonial Medical Reports.—No. 188.—Madras.

ANNUAL REPORT OF THE HEALTH OFFICER OF THE CITY OF MADRAS FOR THE YEAR 1924.

THERE were 21,960 deaths registered during the year, representing a crude death-rate of 41·7, as against 37·8 in the previous year, and the average for the preceding ten years of 42·8. Respiratory causes were the prime contributory causes of the general death-rate, being followed by dysentery, diarrhœa and fever, &c.

Owing to the absence of any epidemic disease in 1924, one would have expected a fall in death returns. Whereas the principal causes of death may be classified under three principal groups, viz., "Infectious diseases," which account for nearly 42 per cent. of deaths, "other respiratory diseases" and "all other causes." Amongst the diseases classified under the first group are diarrhœa and dysentery, tuberculosis, pneumonia, malaria and other fevers, in the descending order of frequency, causes mostly preventable.

"Other respiratory diseases" is shown as a separate group, as they obtain a conspicuous place in our returns, even after excluding tubercle of the lung, &c., pneumonia. Especially it would be somewhat perplexing that so many should die from lung troubles under equable climatic conditions such as Madras uniformly has. It would generally be presumed that respiratory diseases are a special feature of cold countries. While it may be so to a small extent, the exciting causes provoking lung affection have very largely to be sought for in the fact that people live in over-crowded, dark houses where there are the least possible chances for movements of air in and out—ventilation—and where, consequently, they have to breathe an atmosphere continually laden with dust and vitiated by human exhalations and those from the unpaved yards, drains, cesspools, &c.—not to speak of domesticated animals.

The total number of deaths during 1924 exceeds that in 1923 by 2,027, of which nearly 45 per cent. is accounted for by an increase in mortality amongst infants and children under five years and 24 per cent. amongst persons over fifty years of age—age-periods which are more vulnerable to unhygienic and insanitary environments.

The problem lying immediately in front is the urgency for a continued and intensive policy of health reform, whose chief objects are (1) to prevent or remove the circumstances which originate, maintain and propagate disease and bring about death, and (2) to conserve and strengthen the normal physique of the people as a whole, in order that life may be happier and more productive. These objects cannot be achieved by "piecemeal effort, spasmodic endeavour or convulsive action inspired by fear or emergency." They can be of some avail in dealing with outbreaks of small-pox or cholera, but are wholly inadequate if the aim is to eradicate or uproot such plagues from amongst us. The lull is only apparent, the specific infective material is lurking here, there and everywhere, and, given opportunities such as lowered vitality, unfavourable weather conditions and overcrowding, as in fairs, festivals, &c. they flare up into epidemics. So that from year end to year end we are in a continued state of anxious expectancy and preparedness to tackle one infection or another. Preventive measures such as notification, prompt isolation, disinfection, vaccination, surveillance of contacts are sufficiently effective in controlling these diseases, but can have very little influence upon diseases like enteric, diarrhœa, dysentery, influenza and such others as are enumerated to be the more commoner amongst human ailments at present.

The problem of prevention of influenza is in the avoidance of relatively massive or "droplet" infection and can only be practised by individual as well as by communal action; and the public authority, in addition to advising and guiding public opinion and effort on sound lines, should have power to close places of public gathering and entertainments where the continued crowding together of large numbers in close quarters conduces to cross-infections and secondary infections.

The problem of enteric—including in a large measure fevers of indefinite origin—can only be solved in proportion to the wholesomeness of sanitary environment, which can be defined as "the ordinary supply of what is necessary for civilized social life," as concerned, chiefly, with water-supply, sewage, housing, removal of refuse and filth and control of food supplies.

Sir John Simon wrote in 1869:—"Among the circumstances which we find associated in outbreaks of typhoid fever, there is none of more frequent occurrence, none which we are more entitled to consider directly causative of the disease than the consumption of polluted water. It has been one of our most familiar experiences that excremental fouling of wells is, in this respect, amongst the worst dangers which threaten the health of a community."

"Many of the public improvements," wrote Sir George Buchanan as far back as 1866, "have coincided with reduction of typhoid. Though not with absolute constancy, drying of the soil of a town and reduction in the crowding of houses have been followed by reduction of fever. Much more important appears to be the substitution of an ample supply of good water for a scanty and impure supply; other things being equal, the towns in which the substitution has been completed have made most improvement."

Improvement in the reduction of cholera epidemic, diarrhœa and dysentery as well as typhoid can only occur *pari passu* with the improvement of water-supply. Experience in the more advanced countries has shown that the steady decline in enteric is attributable to improved water supplies, sanitation and protection of food. Water, milk or food in general are not necessarily or inherently connected with the ætiology of typhoid fever and "enteric" diseases. They become concerned as they are polluted at the source, or in transit before consumption.

The outlook of tuberculosis is equally limited and would remain invulnerable with the ordinary measure of prophylaxis, which sanitarians usually resort to. There is no single or isolated method of treatment as a panacea. Strict isolation is not only impossible, but ineffective. Disinfection begets a sense of security which is nebulous. Improved environment is not enough; nutrition and open-air life by themselves will not do. The dispensary, sanatorium and hospital in each by itself is inadequate. It is a national evil. It augurs to be one of the most formidable problems of national health; and it calls for a national organization of a specialized tuberculosis service. The preventive attack needs to be comprehensive and should include sanitation, lighting, ventilation, housing and removal of overcrowding, nutrition of the people, the abolition of tuberculous milk, domestic cleanliness and avoidance of spitting in public places and thoroughfares. In short, the vulnerable points in these infections are to be sought for as much in the sanitary environment as in the individual himself.

Causes of Mortality—Infectious Diseases.

Malaria.—Malaria caused 4·4 per cent. of the total deaths, as against 3·9 per cent. for 1923; 971 persons died of this cause, as against 783 in 1923. The disease seems to be on the increase since 1920, especially the northern part of the city suffered more. The question of reorganizing special measures to combat the disease is under consideration.

Enteric Fever.—There were 65 deaths from enteric fever during the year.

The figures can by no means be taken as accurate, since they represent almost wholly those cases notified by the public hospitals; nor do these figures give any indication as to the exact incidence of the disease. Under sub-section (1) of section 330 of the Madras City Municipal Act IV of 1919 it is obligatory on the part of the medical practitioners, hakims and vaidyans in the city to report to the health authorities the occurrence of such cases within their knowledge, but these cases are reported by a few of the medical practitioners and by hospitals only after the death of the patient. The cases that do recover go unreported. Thus a correct record of the incidence of this disease is not available. A good number of fatal cases of fever were probably cases of enteric fever. All the fevers which are not definitely diagnosed are usually reported under the convenient term "pyrexia" and real nature of the disease is unknown. The medical practitioner cannot be entirely blamed for his failure to report cases of enteric fever. Because what usually happens is this: when a person falls ill, the most usual thing obtaining with the masses is to try "home remedies" on him for about a week; when these fail, as they usually do if the disease is enteric, recourse is had to treatment by a vaidyan or a hakim for about another week. Under this treatment the patient either gets worse or rarely recovers. If he dies the case is reported as fever, and if it is worse a medical practitioner is perhaps called in at a late stage. The medical practitioner has then to go about making a correct diagnosis from the clinical symptoms or by bacteriological examination, which means further delay. If, unfortunately, the patient dies immediately, or in the meantime, the case is one of "fever" of unknown origin; and often in reply to our inquiries we are told that the particular medical practitioner was called in just before death, and that no diagnosis was possible. If the case is really one of enteric it will be seen what a great deal of mischief must have been done already in the way of spreading infection through the discharges of the patient, flies and human "carriers," and greater still will be the mischief when one remembers that the stools of the patient are emptied into the house drain or latrine common to a number of tenements, who, moreover, are not in the least anxious or alarmed at the knowledge of the occurrence of such a dangerous infective disease at such close quarters. Thus cases are rarely notified, or are notified so late that prophylactic measures employed can have but little effect inasmuch as a great deal of mischief has been done. Above all, a large number of cases of enteric in this country, unlike in other parts of the world, are treated at the homes, which are mostly overcrowded and ill-ventilated, and obtain little or no bedside care, so much so that by all means facilities for the spread of disease are very prolific

The prevention or eradication of enteric in a word depends entirely or wholly upon a pure water supply abolition of the present dry method of collection and disposal of human excreta, viz., hand removal, trenching or depositing at random, total wiping away of the cesspool and protection of milk and other articles of food.

Colonial Medical Reports.—No. 188.—Madras (*contd.*).

The city water supply, in spite of all that has been done to protect and purify it, is far from wholesome and has been responsible in a measure for high mortality returns and incidence of water-borne diseases, not excluding fevers, diarrhœa and dysentery. The adoption of water-carriage system of excrement disposal seems to be the chief means to improve the state of health of our city as has been the experience of many of the western countries.

In addition to the injurious effect of dust and effluvia the "fly" problem has to be tackled. Flies are known to convey contagion on their hairy legs from infected excreta to some articles of food, in addition to infected dust.

Pending the consummation of such general sanitary reforms devoutly wished for, this disease has to be tackled from the standpoint of the sufferer and his immediate contacts, as is circumscribed by human element. It then is transmissible, (*a*) by those actually suffering, (*b*) by those with the "ambullatory" type, (*c*) by contacts and convalescents, whose fæces and urine contain bacilli and who, as such, act as "carriers" of this disease. The former class constitute a potent danger for the community at large, especially so if they happen to be cooks or servant boys or maids, for without having actually suffered from the disease, they harbour these bacilli and pass them in large numbers with their dejecta. In the present state of knowledge it has been found impossible, even in the most advanced west, to free from the bacilli such persons who are under no sort of control, and measures suggested to minimize the risk of infection are not likely to be carried out in actual practice.

In the case of the patient, all preventable measures are to be taken at the bedside, such as his isolation, disinfection of all his dejecta, the cleaning of the hands of the attendants. The contacts are inoculated with anti-typhoid vaccine wherever possible and kept under observation, in order to save others who, as contacts, may get ill.

Kala-azar.—Fifty deaths were registered from this cause, the corresponding number in 1923 being 52. It is understood that this dangerous infectious fever is somewhat on the increase. It were better if sufferers quickly took to the specific treatment by consulting their physicians promptly. By this means not only are the sufferers cured of what otherwise would prove a fatal illness, but also they are rendered non-infective, and thus safe to the community.

Cholera.—Sporadic cases of cholera are reported from time to time almost during the whole of the year. The rise in the number of cases reported generally depends on various factors, such as (*a*) climate, as it might affect articles of food stored, cooked and uncooked, (*b*) the rise and fall of subsoil water, as it might affect wells, and (*c*) very largely upon the chances of importation of cases into the city. It is observed that invariably few cases begin to be reported early in September and on the heels of the Periapalayam festival and of other festivals in the adjoining district where cases are known to occur. It has also been noticed that soon after the very early and somewhat small showers of the north-east monsoon, the number of cases reported go up. Moreover, during the months of August and September, which are auspicious ones for Hindus, a number of people perform religious vows on account of which they cook an article of food from ragi called "Koolu." This is kept for over two days until the thing gets sour and is then distributed to several people who in turn drink of it during the course of the day or next day. Again, during the last two or three months a special class of fish which is long and thin in appearance, called in Tamil *ola valai*, or colloquially sword-fish, is largely partaken of with rice and more often kept overnight to serve for the following early breakfast. This variety of fish is found in abundance in the near approaches of the sea, especially soon after the first rains of the north-east monsoon, and shoals of which are sold in almost all markets dead cheap; and universally consumed by the poorer classes. There is a noticeable correlation between the incoming of this fish and the reports of outbreaks of cholera cases as cause and effect. In almost all the houses from which cases were reported, it was found that the person or persons partaking of that food were attacked. There were, for instance, five cases in a house in Perambur division in a tenemented house and four cases in one family in Mylapore, 28th division. Food containing this variety of fish, possibly stale, was in all those cases held to have been the exciting cause of the disease. So much so that the city has rarely ever been reported to have been wholly free from sporadic cases of cholera during any year. For the year under review up to November 1 there were reported 75 attacks and 45 deaths.

Small-pox.—Like cholera, small-pox is endemic in the city, one or more cases occurring in a sporadic form throughout the whole year. In short, the health department is required to be continually on the lookout and in readiness to tackle one or other or both of the diseases year after year. There were 665 cases reported during the year, of which 197, or 29·6 per cent., proved fatal, as against 481 attacks and 151, or 31·3 per cent., of deaths during the previous year. As in cholera, the spread of small-pox is certainly or more quickly arrested by prompt isolation. This is but appropriate, as it is, perhaps, the one and the only one amongst eruptive fevers which has the most potent infective material. "There is no contagion so sure and so strong as small-pox; none that strikes at so great a distance."

"In denying any connection between insanitation and small-pox, exception must be made in respect of overcrowding. Like other infectious diseases, small-pox is most easily spread when the most frequent opportunities exist for personal intercourse. It is, therefore, most often met with and greater in amount in busy centres of population than in

scattered rural districts," says Sir Arthur Newsholme. This statement can nowhere be better demonstrated than in this city. During the epidemic of small-pox in 1922, the first three divisions were badly affected. People living in these divisions are of the poorest classes, almost the whole of them living on wages which they earn by daily labour. Each family lives in a single room in a house containing five or more tenements. Many others house themselves in huts and billets covered around and on top by palmyra or other leaves. Apart from their being exposed to the vicissitudes of weather, the sanitary environment under which they live is entirely unwholesome. There is an overcrowding in such tenements that creates and harbours filth which actually breeds disease. More cases are time and again reported from the overcrowded parts within the heart of the city than from its outskirts, although socially and economically the people of the former areas are more favourably situated than those of the latter. The reason is obvious. People living at the outskirts, whatever their poverty and kind of housing, &c., have assuredly a freer and more abundant air and open space and less overcrowding, whether they like them or not.

For some months past it has become more and more apparent that amongst the cases which are returned as small-pox there is a fair proportion which are not by any means typical of small-pox as usually met with in this country—even when modified by vaccination. Nor are these cases akin to chicken-pox either. The initial symptoms are not quite so mild as in chicken-pox and not so severe as in small-pox. The fever rarely goes above 102° F. and the rash appears simultaneously with the fever or a few hours after as small spots and in regular sequence (successive crops), usually first on the forehead, then on abdomen and back, chest and extremities. The relative proportion of the number of pocks is far greater in the abdomen and back than in other parts of the body, and there are particularly few on the hands and feet. The vesicles are usually dome-shaped containing a scanty amount of dull, white, clear watery fluid (not clear as in chicken-pox), looking as if the skin were bespattered with tiny acne spots. There is no primary umbilation and the individual pox grows to a size somewhat smaller than is ordinarily known in cases of small-pox or chicken-pox. The further evolution is rapid, the pustular stage supervening within 24 to 36 hours after the appearance of the vesicle and each pustule containing but a tiny whitish pus-like bead, and pricked it does not collapse so readily as in chicken-pox. The initial fever does not disappear on the appearance of the rash, but continues between 100 and 102 degrees for two or three days, at the end of which all the symptoms subside so completely that the patients feel quite well and anxious to move about. There is no secondary rise of temperature coincident with pustulation as in small-pox. In fact, after the third or fourth day from the commencement, the patients complain of no other inconvenience than the irritation due to the presence of the eruption. The eruption in point of its extent, development and distribution is quite unlike that in chicken-pox. The pox begin to dry up from the eighth or ninth day until the fourteenth or fifteenth day from the date of onset of disease. There is no pitting and the scars disappear in a week or two. The majority of cases have been amongst young adults, especially those belonging to the west coast. Three children between the ages of 7 and 10 were found to exhibit these signs at hospital and all the cases bore very good marks of successful vaccination. It is reported that the protective power of vaccination does not appear to be of so definite a character as in ordinary small-pox, although vaccination reinforced by recent vaccination is stated to confer protection.

The signs and symptoms described above are closely akin to a description of a similar disease investigated in parts of South America and the West Indies and called by the term "Alastrim." These circumstances have been reported to the Director, King Institute, Guindy, who has kindly undertaken an investigation in this matter.

Measles.—There were 32 deaths during the year.

Influenza.—The total number of deaths registered under influenza was 14 for the year, against 19 in 1923.

Plague.—No case of plague, either imported or indigenous was reported during the year.

Diarrhœa and Dysentery.—3,700 deaths were recorded during the year from these causes. The largest number of deaths were recorded in January, August and October.

Diarrhœal diseases are almost entirely waterborne and a fall in their incidence can only follow in proportion to the extent of the improvements that can be effected in the purification of our water supply and the control that can be exercised on the sale of articles of food and drink.

General Respiratory Diseases, excluding Tubercle of the Lung.—4,130 deaths were registered from this cause. The number of deaths from these causes has been the highest since 1919.

Tuberculosis, including Tubercle of the Lung.—1,468 deaths were registered under this head, or 200 deaths more than in the previous year.

Relapsing Fever.—There were 5 cases of relapsing fever reported during the year, and all of them were imported.

Control over Waters.—Ever since the reduction of the establishment under "malaria" mosquitoes have not ceased to flourish nor has malaria gone down. Madras City still continues to be an endemic area for malaria, and everyone who has the welfare of the city at heart should feel anxious to rid the city of this "scourge." Malaria is perhaps the only disease whose inroads into the human system are so insiduous and often unfathomed that it sooner or later saps the vitality of human beings and kills them far too prematurely. Suitable provision must be made for a special staff to carry out remedial and preventive measures, such as cleaning

of tanks and wells and such other breeding grounds, special attention being paid to the eradication of water hyacinth, petrolizing tanks, ponds, marshes and wells and reclaiming them wherever possible, introduction of larvicidal fish, drainage of water-logged lowlands; in short, eradicating by all possible means every breeding ground of mosquitoes of whatever denomination—malaria or non-malaria —for as human blood-suckers they are as great a danger as any other public nuisance; and not until this is done can the Corporation think of rooting out malaria from the city, for malaria has been demanding a great toll of citizens' valuable lives.

The Cooum and the Buckingham Canal, the two "meandering cesspools," still continue to be offensive, although the Government (P.W.D.) has been petitioned several times for their proper maintenance. Probably it is neither practicable nor economical to carry out any spasmodic efforts at cleaning these waterways short of dredging them and this cannot be done until a good flush and flow from the upper reaches can be ensured. But in any case, until some practical solution of rendering these neat and clean is carried out the city must suffer from its odours and the insect pests that breed in them.

A Practical Scheme for Securing the Supply and Distribution of Clean, Unadulterated Milk in a Large City.

(1) A pure, unadulterated, and abundant milk supply, readily procurable by all classes, is one of the essential factors in any sound scheme of nutrition. Adequate nutrition ensures proper growth and development of the body, and increases its resistance to disease. No single article of diet other than milk combines so well the necessary constituents of food required, especially by young and growing children. To these cow's milk is next best to mother's milk. And yet milk is perhaps the one article of food the proper use of which is almost entirely unknown to large sections of the population. Milk again is an article that is easily adulterated; whether this be by mere addition of water, partial extraction of fat, addition of preservatives, contamination by dirt and filth, milk retains its natural "milky-white" appearance, and man is easily deluded into false security. The average daily milk consumption of the population in general is not more than an ounce per head. Unlike in the west, large sections of people partake of curd buttermilk prepared from milk, which, being generally diluted, is of little nutritional value, although it unquestionably is an invaluable adjunct for promoting digestive functions and for supplying those valuable accessory food factors—vitamins.

(2) It is difficult to assess the exact causes contributing to the neglect of this valuable dietary. Ignorance as to its food value is undoubtedly the first; secondly, there exists the misconception that milk causes indigestion; thirdly, there is a traditional belief, at least in South India, that in children milk causes katti—enlargement of liver and spleen —which really is an independent condition called hypertrophic cirrhosis of liver. Possibly milk is a channel of infection due to its reaching the consumer in grossly adulterated and unwholesome condition. Town populations seldom use milk at its best; too often encounter it at its worst, when filthy, stale or sour. Almost all the milk distributed for consumption is produced under extremely insanitary conditions and is liable in course of production, handling, and distribution to gross contamination by dirt. It is often infected with disease-causing germs such as tubercle or typhoid. Such is the milk consumed by young infants, delicate children and invalids. Amongst the infectious diseases of man communicated by animals, tuberculosis is by far the most important, and although there is little or no direct evidence in this country, experience and investigation in other countries have established that bovine tuberculosis is conveyed to the human subject through milk. Milk, even after sterilization, is liable to contamination for want of efficient storage. The milk problem is a formidable one bearing directly on the health of the community. Briefly stated the key to future improvement depends upon:

(1) Encouraging production of larger quantities of milk and increased consumption, especially in the young.

(2) Improving the quality of milk, as regards freshness, nutritive value, unadulteration and freedom from danger to health.

(3) Before suggesting remedial measures for improvement, it is necessary to review existing conditions regarding milk, its production and supply. Throughout the length and breadth of this country systematized dairying as a profession or trade does not exist. It is almost wholly in the hands of petty dealers or householders who keep a few animals, just enough for a bare living. The father attends to the milking of animals, their upkeep and sale of milk; the womenfolk assist in getting the curd and butter (for ghee) and hawk these about. The average milkman is heavily encumbered, and is continually in the clutches of the moneylender.

(4) Success in dairying depends chiefly upon the proper selection of the dairy herd. Cows whose milk-yield is low, whose dry period is long and which are irregular in calving, cannot but increase the cost of production of milk. The best animals in South India are bad enough, there being three breeds at least, viz., Kangayam, Ongole and "Cross-breeds." The Kangayams are the worst, and the "Cross-breeds" the best milkers; the Ongoles are fairly steady, yielding an average of two measures or nearly eight pounds daily. The quality of milk, especially its fat-content, varies in accordance with the stock and available food. In Madras and the South the chief food is paddy-straw and gingelly-cake; in the Northern Circars and almost the whole of North India cotton-seed, cholam, or wheat-stalks. Milk of the Northern animals is comparatively rich in quality.

(5) From a business point of view the maintenance of buffaloes purely for milk would be a

step in the right direction. Popular sentiment, however, in this Presidency is against buffalo milk as unsuited to children. Its use is restricted to the extraction of fat directly, or after conversion into curd or buttermilk. In other provinces its value is greater, since it is used in large quantities for preparation of the sweets so largely consumed by the people. Another important fact hindering successful dairying is that milk cannot be produced at long distances from centres of population. In addition to the want of railway and other facilities for quick transport, milk undergoes rapid changes in this country, and becomes sour within about twelve hours after production, especially amidst the unhygienic conditions generally prevailing. It becomes further contaminated in the home for want of proper care and protection.

(6) From these circumstances, combined with the facts that there are no suitable penalties for adulteration, and that the public demand a large measure for a small sum, springs the whole system of adulteration and fraud. The adulteration generally consists of adding water or buffalo's milk after removing fat and diluting suitably. Undoubtedly, the dairyman could not live but for the adulteration he practises. The problem of adequate milk supply has therefore to be considered from the aspect not only of public health, but also of economics. If milk is to be supplied unadulterated, then to make production economic, (*a*) the price must be increased, or (*b*) better business methods introduced and good milking-stock bred. Perhaps under existing economic conditions comparatively few people can pay an increased price. The public need to learn that, in comparison with other fat and protein-yielding foods commonly employed by poorer classes, pure, wholesome milk has always been relatively cheap; more especially should people learn that milk plays an important rôle in dietetics as a "protective" food, in supplying the food-accessory substances (vitamins) which are required for growth of the body and for its preservation from certain affections and which are liable to be wanting in other articles of diet. With better business methods pure milk can be supplied at current prices.

(7) Milk for human consumption should be pure, clean, wholesome and unadulterated, drawn from healthy cows under sanitary conditions; drawn by a clean method of milking into clean vessels; cooled at the farm; protected during transit, delivery and in the home, from all forms of infection and contamination. Control can be exercised (*a*) by the *sanitary authority* effectively administering local powers of control over adulteration, uncleanliness, infection; (*b*) by the *dairy trade* working on economic, clean and scientific business lines; (*c*) by the *consumer* demanding pure milk, he himself protecting it from contamination; (*d*) by *commmunal enterprise* producing or demanding 'certified" milk.

(8) This fourfold control cannot obviously be practised by individuals. The question is one of national importance, and calls for a national policy; for "malnutrition is wider in incidence and more devastating in issue to a community than food-borne disease." An enlightened milk policy should aim at the following: (*a*) To economize cost of production in order to (i) increase its consumption, (ii) bring supplies within the reach of the poorest families; (*b*) to improve and control hygienic production and quality; (*c*) to educate the public with regard to the nutritive properties of milk; (*d*) to increase supply in order to meet the extended consumption which should follow improved quality and public enlightenment; and (*e*) to prevent exploitation of the producer by combination or trust.

(9) Dairy farming should be developed as one of the most important, productive, stable and economic branches of agriculture. The broad lines of hygienic milk reform are: (*a*) Clean, effective dairying at the farm and the retail dairy—the supervision and control of milk production at the source; (*b*) improved methods of distribution to avoid deterioration and loss through souring, &c.; (*c*) stringent legislation and effectual administration of Milk and Dairy Orders, regulation of milk under Food and Drugs Act, control of *condemned* milks; (*d*) proper care and protection in the home.

(10) Unfortunately in Indian towns there are material differences in methods of dairying and supply. While in Northern India milk and milk-products produced in the byre are conveyed to milk and curd shops (dood and dahi khanas) and there retailed to consumers, in Southern India milk is either produced at the consumer's house in his presence or conveyed by the producer or his agent, when it is invariably adulterated. In a country where every particle of surplus milk may be converted into curd or buttermilk, dairying ought to be easy and profitable. Curd, buttermilk and ghee—all milk products—are daily articles of Indian dietary, especially vegetarian dietary.

(11) For reasons already enumerated, it is somewhat difficult to propound a scheme for universal adoption in Indian towns. The only means of meeting the situation is to organize dairying as a business concern. Dairy farming, coupled with breeding of stock, would improve the milking capacity of cows and make the whole concern profitable. A dairy farm should preferably be located on the outskirts of the town for which the supply is intended. There should be sufficient pasture land available for immediate grazing and future extensions. The dairyman, who in his own interest should live on the premises, should not only produce the milk at the farm under sanitary conditions, but should also provide facilities for transporting it to the several shops where it is sold by retail or to registered customers. The milk immediately after it is drawn from cows should be mixed, screened, put in suitable covered cans, locked and sealed, and placed in cold storage awaiting dispatch. For smaller consumers who contract for a regular supply daily, the milk should be canned or bottled at the dairy, and delivered at their houses.

Colonial Medical Reports.—No. 188.—Madras (*contd.*).

Cans or bottles should be in duplicate; while one with milk is delivered, the empty is returned to the farm for cleansing and use for the next supply. These cans should have good locks and duplicate keys, one with the dairyman or manager, and the other with the householder. All utensils in the dairy or shop should be thoroughly sterilized in boiling water or steam before being brought into use. The utmost attention should be paid to minutest details to achieve two ends; (1) to prevent contamination, the chief sources of which are the udder and teats of the cow, the hands of the milker, the atmosphere and utensils and vessels in which the milk is collected and transported; (2) to prevent fraud and adulteration at all points from production to delivery to consumers. Retail shops should be opened at public and private markets and at other places reasonably approachable. Fresh milk should be available both in the mornings and evenings. All surplus milk should be promptly curdled or defatted, and the resultant produce sold at the shops or to professional hawkers. The dairy should have a creamery, and the butter manufactured sold as such or as ghee. There should be one or more motor or horse-drawn vehicles for quick transport to shops and for house-to-house delivery morning and evening.

(12) Effective pasteurization for sterilizing milk before delivery needs great care and technical skill; as practised even in England, it is considered unsatisfactory and unreliable as a means of protection to the consumer. The range of temperature should be such as not only to ensure destruction of pathogenic bacteria within the limit of time of exposure, but to preserve taste, physical properties and its vitamine-content. Moreover, fresh milk is more resistant to growth of bacteria than that which becomes infected after pasteurization. Milk produced under clean conditions, properly cooled and despatched in clean, airtight vessels will retain the property of freshness long enough for all ordinary purposes of transport, delivery and household storage. "Freshness in milk is in common experience determined less by age than by the care and cleanliness with which it is produced and subsequently handled."

The average Indian will not purchase anything but raw milk, which he generally boils before use.

(13) Dairying means heavy money outlay, and want of money is a great obstacle to public health progress. Dairying should be started on Joint Stock Company or an Co-operative lines. Where an enterprising person comes forward to start a dairy, the State should encourage him and afford facilities by securing enough land free or at a nominal rent—at least until the business is established.

To be more paying and to keep down average cost of pure milk, it is desirable to have a few she-buffaloes (about 20 per cent.) of good stock, yielding large quantities of rich milk, as the products thereof, viz., butter, ghee and curd, find a ready sale and bring in quick returns. Within a few years stock may be bred on the farm. There should be two or more breeding bulls of high pedigree, imported if necessary, for cross-breeding. Herd and pedigree registers should be maintained and unprofitable cows weeded out. Bulky, concentrated food should be prepared previously. Milking herd should be stall-fed and allowed to graze on green pastures. Dry herd and young stock should be put out to graze freely, as this would tend to economy in upkeep. They should be properly housed in airy, well-ventilated, paved sheds, cared for and supervised. The creamery and store-room should be strictly fly-proof. All dung, manure, &c., should be regularly collected, stored away from the sheds, then sold or used as manure. He-calves should be fattened and sold for profit; cow-calves added to the herd.

(14) The number of such dairies required for a town depends upon the population and demand. At the same time it would be impracticable to wipe out at once the petty trader. The existing unsatisfactory, unhygienic conditions should be removed by rigorous administration of statutory legislation governing dairies, cow-sheds, milkshops, &c. These people should be educated to understand that a dairy where animals are under ideal sanitary conditions, and where milk is produced under scrupulously clean conditions, will, in the long run, be more paying than those located in congested localities where animals are overcrowded in filthy yards and where cleanliness is impossible; animals in the former will be healthier and longer-lived, and they will yield comparatively more milk with better keeping qualities than in the latter, where on account of sickness and probable death of animals, dairying would be unprofitable and impossible. The local authority could also assist such people by constructing and letting out on normal rents sanitary byres to accommodate a hundred animals each in different parts of the town.

(15) Effective legislation should have precedence over everything else. To increase consumption milk should be attractive, appetizing, with good keeping qualities and of recognized economic value. These problems involve the passing of Dairy Orders and Regulations and their effective application.

Legislation to control and regulate milk supply should be all-comprehensive and embrace the following:—(1) Registration by the sanitary authority of all persons carrying on the trade of cow-keepers, dairymen, purveyors of milk and their licensing. (2) Regulations prescribing paving of floors, lighting and ventilation, airspace, cleaning, drainage and water supply in the dairy and cow-shed. (3) Securing cleanliness of milk-store, milk-shops, sterilization of all utensils. (4) Cleanliness in milking, by thorough washing of udder and teats of cows, and (5) Precautions to be taken by dairymen, purveyors of milk and salesmen against infection or contamination at all stages. (6) Periodical and regular inspections by the sanitary authority and veterinary inspectors with regard to (*a*) health of cattle, (*b*) prevention of sale of milk from diseased animals, (*c*) weeding out tubercular ones. (7) Prevention of dairying in or upon living premises, and prohibiting

persons suffering from infectious diseases from taking any part in the trade. (8) Adequate facilities for keeping milk cool and for prompt and speedy transit and delivery. (9) Regulations for preventing aduiteration and impoverishing milk of its nutritive value; fixing of standards, milk not sold as skimmed, separated or condensed milk should be presumed to be not genuine if it contains less than (*a*) 3 per cent· milkfat, (*b*) 8·5 per cent. milk solids other than milkfat. Use of preservatives wholly interdicted. (10) The sale and use of condensed milk should be discouraged by every means, and its use for infants and invalids prohibited.

(16) Last but not the least important is prompt care and protection of milk in the home. Pasteurizing at the home is conveniently effected thus: Place the milk can, well-stoppered, in a deep saucepan, put some very hot water, put over fire until water comes to the boil. Remove saucepan and set aside for fifteen minutes; then cool rapidly. The temperature of milk barely exceeds 170° F. and its physico-chemical properties are not changed. The method is fool-proof. Milk should never be boiled. The can should thereafter be kept in a cool place, well covered and protected from flies, dust and other contamination.

In short, the consumer can control his milk supply by his demand; the trade ought to meet the demand; the local sanitary authority should play an active part in its control.

Colonial Medical Reports.—No. 189.—Bihar and Orissa.

ANNUAL RETURNS OF THE HOSPITALS AND DISPENSARIES IN BIHAR AND ORISSA FOR THE YEAR 1924.

By Lieut.-Colonel J. MASSON, M.B., F.R.C.S.E., I.M.S.

Officiating Inspector-General of Civil Hospitals, Bihar and Orissa.

THE year opened with 546 and closed with 580 hospitals and dispensaries of all classes, an increase of 34 against 61 in 1923.

The number of patients treated at the State public, local fund and private aided dispensaries rose from 3,586,552 in 1923 to 4,102,732 in 1924 The increase of 516,180 took place in the general and standing dispensaries.

The remarkable decrease in the attendance at the travelling dispensaries was due to the closure of some of these dispensaries whose retention was considered no longer necessary.

DISEASES.

The year under report was not so healthy as the previous one, the death-rate amongst the general population being 29·10 against 25·00 per mille. The increase in the mortality was for the most part due to the prevalence of cholera and small-pox in epidemic form during the year in several districts of the province.

Cholera.—The number of deaths from cholera amongst the general population which had decreased from 26,805 in 1922 to 8,198 in 1923, rose to 77,480 in 1924. The attendance at the hospitals and dispensaries also increased from 3,697 in 1923 to 25,435 in 1924. It is, however, satisfactory to note that in spite of the large increase in the number of patients admitted into the hospitals, the number of deaths amongst them was much less, being 344 only, as compared with 315 in 1923.

Plague.—This was less prevalent in 1924, the death-rate being ·3 only, as compared with ·8 per mille in 1923. The number of patients treated at hospitals and dispensaries was 3,298 with six deaths, against 4,770 and sixteen, respectively, in the previous year.

Small-pox.—The death-rate from small-pox was ·2 against ·09 in the preceding year. The dispensary attendance also increased from 407 to 675.

Malaria.—The total number of patients treated for malaria in hospitals and dispensaries was 1,139,005, as compared with 932,508 in 1923. These figures are in keeping with those for deaths amongst the general population from fever which numbered 660,635 and 599,840 respectively.

Influenza.—23,104 cases of influenza were treated in hospitals and dispensaries in 1924, against 26,439 in 1923. As in the previous years, vaccine was supplied by Government free of cost to all civil surgeons and superintendents of jails for use in the institutions under their control.

Venereal diseases.—The number of patients treated for venereal diseases decreased from 64,172 to 63,821. The grant of Rs. 12,000 sanctioned by Government for affording special treatment of these diseases was distributed to all Sadr hospitals and also to those sub-divisional hospitals where assistant surgeons are employed. The money allotted is spent with good result.

Kala-azar.—28,669 patients were treated for kala-azar in 1924, against 20,619 in 1923. The treatment by intravenous injection is being continued as usual. Arrangements are now being made for the treatment of this disease with orea stibamine, which is considered as being the most serviceable antimony preparation at present available.

Tubercle of the lung.—The proposal for the establishment of a sanatorium for the treatment of

tubercuIosis cases at Sabour has been abandoned as this place is not considered suitable for the purpose. An annual grant of Rs. 1,500 has been sanctioned by Government to the King Edward Sanatorium Dharmpore (Simla), for reserving one bed for the non-paying patients from this province. A scheme for the establishment of a sanatorium at Itki in the district of Ranchi has been put forward and is being considered. During the year under report 10,333 patients were treated in hospitals and dispensaries in the province against 8,924 in the previous year.

Filariasis.—The Filariasis Hospital at Puri was primarily instituted for the investigation and treatment of filariasis, but its scope has been considerably extended, and there is now in existence a compact unit doing magnificent work. All injections are carried out here. The three main investigations now conducted relate to (1) filariasis, (2) ankylostomiasis with the allied *Necator americanus*, and (3) *Strongyloides stercoralis*. In Orissa it seems essential that the latter parasites should be thoroughly investigated, as they probably account for the poor physique of the Oriyas

Leprosy and Leper Asylums.—In accordance with the resolution brought forward in the local Legislative Council in 1923, additional facilities for the treatment of leprosy at Sadr and sub-divisional hospitals have been introduced and the scheme is being given a fair trial. The results obtained will be reported in due course. The asylum at Lohardaga having been closed, there were nine asylums only at work and 8,225 lepers received indoor treatment at these institutions in 1924.

Operations.

The total number of surgical operations performed during the year under review at the State public, local fund and private aided hospitals and dispensaries was 249,507 with 378 deaths, as compared with 206,814 operations and 346 deaths respectively in 1923.

Radium Institute.

The work at the Ranchi Radium Institute has been carried on very satisfactorily under the management of Lieut.-Col. J. C. Vaughan, I.M.S. (retired). Two hundred and fifty-three new cases were treated during the year, against 189 in 1923.

Colonial Medical Reports.—No. 190.—Bihar and Orissa.

ANNUAL REPORT ON THE WORKING OF THE PATNA MENTAL HOSPITAL IN BIHAR AND ORISSA FOR THE YEAR 192

By H. R. DUTTON, M.R.C.P.Lond., D.T.M. & H.Camb., Lieut-Colonel, I.M.S.

Superintendent Patna Mental Hospital.

Population.

The number of patients at the commencement of the year under review was 284, i.e., 237 males and 47 females. Sixty-three males and 7 females were admitted during this year, against 65 males and 4 females (including two cases of readmission) in 1923. There were no cases of readmission during the year.

Recoveries and Discharges.

The total number of recoveries was 35. Besides, 2 were transferred to Gobra Leper Asylum (Bengal), 1 was made over to friends having improved, and 1 was so discharged "not improved." There was one case of escape.

The question of discharge of those patients (mostly females) who have recovered but are more or less friendless and homeless, is a difficult problem to solve. It is considered unwise to throw them out on the world, because if discharged the stigma of being in a mental hospital is likely to stand in their way of getting any employment or a shelter and in consequence they will gradually swell the number of beggars, or most likely of criminals or "readmitted" cases On the other hand, all authorities agree that they should never be kept within the precincts of a mental hospital where the surroundings are certainly not congenial and common humanity demands that they should be segregated from insane persons as soon as they are convalescent. Under existing conditions they soon contract an "asylum habit" and thus become a continuous burden to the State.

The desirability of construction of separate convalescent wards, outside the boundary wall of the hospital, is therefore suggested for the consideration of the Government, and the opening of classes in various branches of home industry under a properly trained work-master and work-mistress, and attention is drawn of the generous public to the urgent necessity of starting "Homes" and agricultural farms for these unfortunates.

Sickness and Mortality.

Three hundred and seventy-six patients, viz., 290 males and 86 females, were treated for diseases other than mental against 430 in 1923. The main diseases during the years 1921-24 show a decrease in their incidence, i.e., dysentery, influenza, malaria, ankylostomiasis, diarrhœa, tuberculosis, cholera.

Of 17 cases of ankylostomiasis, 8 were admitted

in the mental hospital with the infection, and 1 case was infected while staying in the hospital. The remaining 8 were from old cases who had recovered under treatment (several examinations of stool at different periods giving negative result) but amongst whom the disease either recurred or who reinfected themselves during the year.

It is always a difficult problem to keep down the incidence of ankylostomiasis and dysentery amongst the patients of a mental hospital, quite a considerable number of whom are of filthy habits, passing stools in wards, open paths or in the fields, drinking drain water, eating garbage and leaves, and are also of coprophagic and geophagic habits. Of tuberculosis 3 cases were admitted with infection.

There were 5 deaths, against 20 in the previous year. There was no case of death amongst the "Observation" cases. From available records it appears that the death-rate in 1924 has been the lowest since 1912.

Criminal Lunatics.

In this connection a few observations must be made in regard to "criminal lunatics." Except in those cases where the accused persons are too insane to draw the attention of the trying courts as to their mental condition, a plea of insanity is taken by the defence after some time has elapsed since the commitment of the crime, and the court then directs the investigation of the mental condition of the accused. It becomes an extremely difficult problem for the medical men concerned to form any opinion at the stage as to whether or not the accused was of unsound mind at the time he committed the crime, and even if he was so whether his unsoundness of mind was of such a nature as to have negatived his criminal responsibility. There is a possibility of miscarriage of justice one way or the other in such cases. Or cases may occur where no such plea of insanity having been taken, and the mental disorder being of a trivial nature at the time of trial to escape attention of the court, people have been convicted, but while in prison undergoing the sentence they show unmistakable signs of such types of mental disorder which cannot but be of a long standing in nature. Amongst people convicted of crime, but later showing symptoms of insanity, some suffer from dementia præcox, epilepsy and dementia paranoides. Now all will agree that the diseases mentioned above are of very, very long standing in nature, starting possibly from childhood. It becomes then a pertinent question to ask as to whether or not these crimes were the direct result of their diseases, and if so they should not have been convicted at all. Then again the question of "malingering" mostly among the convicts is a problem to be always kept in mind, the detection of which requires special observation and knowledge of mental disorders on the part of the prison authorities. It is not infrequently that cases of malingering have been mistaken for true insanity due to either want of special knowledge or intelligent observation or confusion of the convicts with the warders staff.

To obviate the above-mentioned defects all prison doctors should undergo a thorough post-graduate training in a mental hospital, and that they should examine and record the mental condition of all prisoners, specially the under-trial prisoners, no matter whether a plea of insanity is taken or not. And in case of the latter, if they have reason to suspect any unsoundness of mind, they should voluntarily inform the trying courts their findings and opinion.

Form of Insanity.—The principal types of insanity among the patients admitted during the year 1924 were imbecility, dementia præcox, manic depressive, confusional insanity, epilepsy, paranoia and dementia paranoides.

Etiological Factors.—One case was admitted who developed insanity shortly after an acute attack of malaria, and whose blood examination at the time of admission showed the presence of numerous malignant tertian parasites. His father was of a neurotic temperament, as was subsequently admitted by the patient, but in my opinion malarial toxin was the exciting cause. The other common causes were puberty and adolescence, climacteric, senility, child-bearing, mental stress and strain, malnutrition and starvation.

Race.—Fifty Hindus, 12 Mohammedans, 3 Indian Christians and five of other castes were admitted during the year.

Clothing and bedding.—An attempt has been made to issue dhoties, shirts and coats to all patients instead of the regulation prison garb formerly in use, viz., janghias and kurtas. Flannels and tweeds of various shades were purchased and warm coats were prepared locally, introducing greater variety of pattern and individuality in fitting. Sufficient number of blankets were issued, but no bedding could be provided owing to stringency of funds.

Diets.—An improved scale of diet was introduced and the total amount as well as the amount of staple articles of diet were sufficient. Milk was given to the vegetarians in place of fish or mutton. But I regret to say that the diet generally suffered from a depressing monotony owing to the lack of a properly equipped kitchen and insufficiency in number of trained kitchen workers. Much cannot be expected from one cook getting a pay of Rs. 12 who has to cook for 300 patients daily.

Amusements.—Due to the want of a recreation hall and available space for outdoor games "amusements" could not be properly developed. Patients were taken in batches to a theatrical performance which they enjoyed immensely. Musical instruments, gramophone records and playing cards were issued to them. The therapeutic effect of properly conducted amusements and of indoor and outdoor games cannot be overstated and it is hoped that in the new hospital at Kanke this department will be properly developed.

Colonial Medical Reports.—No. 191.—New Zealand.

MANDATED TERRITORY OF WESTERN SAMOA. ANNUAL REPORT OF THE DEPARTMENT OF HEALTH FOR THE YEAR ENDED MARCH 31, 1925.

By T. RUSSELL RITCHIE,

Chief Medical Officer.

Public Health.

The previous year was marred by an epidemic of bacillary dysentery, but this year has been the most satisfactory one experienced for many years. The territory was singularly free from serious illness or even minor epidemics. The figures given in the table of attendances at the hospitals and dispensaries throughout the territory do not indicate any increase in sickness. The natives freely avail themselves of the facilities offered for treatment, and report for very minor complaints.

Infectious Diseases.

The return given does not include all cases of infectious diseases occurring in the territory, but only those which have been reported by European medical officers, i.e., enteric fever, pulmonary tuberculosis, lobar pneumonia, broncho-pneumonia, measles, dysentery, influenza, leprosy, puerperal fever, chicken-pox, mumps, tetanus, gonorrhœa and erysipelas.

Note.—Of the twenty-eight cases reported as enteric fever, in only eight was the diagnosis confirmed by bacteriological or serological investigation. Of the forty-two cases of pulmonary tuberculosis reported, the vast majority are cases diagnosed clinically.

Ankylostomiasis.—During 1923, slightly over eighteen thousand natives were treated for hookworm. The treatment was then discontinued, as the pressure on the department for the treatment of yaws made it impossible to carry out both campaigns with the staff available. During 1924 fresh supplies of drugs were purchased from the International Health Board (Rockefeller Foundation), and treatment was recommended in November. During the remaining five months of the year 16,205 natives were treated.

Yaws (Framboesia tropica).—In April, 1923, as a result of the natives agreeing to a medical tax of £1 per adult male, free medical treatment was instituted, and steps were immediately taken to organize a systematic campaign against this disease. Although a considerable amount of work had been done before that date, systematic work was impossible, as most of the natives were not prepared to pay the charges made for treatment. This preliminary work was of value in disseminating amongst the population a knowledge of the (to them) miraculous results obtained from injections of novarsenobillon. It was found impossible to cover the whole territory in the year, but in those districts attended to 32,366 injections were given. This year the whole area was covered, and 21,222 injections given. The figures are more instructive when given in a different way. The "first round"—that is, the treatment of the whole territory for the first time—resulted in 36,304 injections being given, covering a period of fifteen months. The figure for the "second round" was 17,284. During the first round numbers of small children with primary and commencing secondary lesions were not offered for treatment, but during the year under review such children were offered much more freely. Such an impression was made on the natives by the results of treatment that the Fono of Faipules, or native advisory body, agreed to the introduction of stringent regulations for the control of this disease, and these regulations have now been passed by Order in Council in New Zealand, and will be enforced during the coming year.

Filariasis.—The Research Expedition of the London School of Hygiene and Tropical Medicine, under Dr. P. A. Buxton, continued its work during the year.

Leprosy.—During the year seven lepers were transferred from Samoa to the Leper Asylum on the Island of Makogai, in Fiji. These consisted of four Samoans, one half-caste French Samoan, and two Chinese labourers, all males. Two lepers, both male Samoans, died at Makogai during the year.

The number of lepers from Samoa under treatment at Makogai at the end of the year under review was: Samoans, five males, one female; half-castes, two males, one female; Chinese, five males; Rarotongan, one male; total, thirteen males two females.

In addition to the above, five lepers (one male and two female Samoans and two male Melanesians) are isolated in Western Samoa pending transfer to Fiji after the hurricane season has passed. While awaiting transfer these lepers are under treatment.

Vital Statistics (Samoan).

The year under review has been an exceptionally satisfactory one. The number of live births (1,900) constitutes a record for Western Samoa, and the number of deaths (766), although not a record, is well below the average. The marked absence of serious sickness and even minor epidemics, the provision of dispensaries in outlying districts, and the campaigns against hookworm and yaws, are all

factors in helping to bring about the present position. The reduction in the number of adults due to the influenza epidemic of 1918, and the increase in the percentage of children in the community, tends to an increase in the death-rate, but it is hoped that the child welfare campaign to be commenced during the coming year will gradually produce the opposite effect.

Population.

During 1924 the natural increase amounted to 1,134. The population at December 31, 1924, was estimated to be 34,817.

Births.

The births of 1,900 living children were registered during the year. This number of births is a record for Western Samoa.

Deaths.

The number of deaths registered during 1924 was 766. Last year's figures were abnormally high, owing to an epidemic of dysentery (bacillary). This year the number of deaths is considerably below the average. With a birth-rate of 55·38 per thousand it was to be expected that there would be an increase in the number of children dying in the first year of life. That such did not happen is shown by the infant mortality rate being only 155 per thousand births, a figure considerably below the average, and one which compares favourably with many more advanced communities. Since the chief loss of life in Western Samoa occurs between the ages of six months and two years, it is anticipated that the coming year will not be as satisfactory as this one, but steps are being taken to reduce the wastage at this period of life.

Report on the Laboratory, Government Hospital, Apia.—April, 1924, to March, 1925.

By P. A. Buxton, M.R.C.S., L.R.C.P., D.T.M. and H.

(*Expedition to Samoa from The London School of Hygiene and Tropical Medicine.*)

The laboratory has been mainly busied with research into filariasis and other conditions, and the research work is not included in this report. We have also dealt with such specimens as have been sent in from the wards and out-patient department, and it is these specimens alone which are the subject of this report. The following examinations have been made:—

Blood Examinations.—For filaria, 23; for filaria (positive), 7; red count, 1; white counts, 5; differential white counts, 25. Blood-cultures: negative, 8; positive (*Bacillus typhosus*), 1. Agglutinations: negative, 30; positive (*B. typhosus*), 9; (*Bacillus paratyphosus* A) 3; (*B. paratyphosus* B) 2.

Fæcal Examinations.—For worm-eggs: negative, 53; hookworm present, 96; trichuris, 55; ascaris, 24. For protozoa: negative, 8; lamblia present, 1; *Entamœba coli*, 3; *Entamœba histolytica*, 1. For bacteria: number plated, 26; *Bacillus pyocyaneus* found, 2; *B. paratyphosus* (non-agglutinating), 1.

Urine Examinations.—General, 133; for organisms, by smear, 3; for organisms, by culture, 2.

Various Examinations.—For leprosy: total, 26; positive, nasal smears, 3; skin-scrapings, 3. Pus: cultures, sundry, 15; smears, sundry, 16; smears, urethral, 8; smears, urethral, gonococcus, positive, 5. Gland-punctures, 3. Serous fluids examined 4. Smears from yaws cases, 25. Sections cut, 12. Post-mortem examinations, 4. Fluids for percentage of alcohol, 9. Sputa for T.B.: negative, 32; positive, 8; streptococci, positive, 1.

The following points deserve comment: There are a number of cases which clinically resemble typhoid, but from which no organism can be recovered by blood-culture early in the disease; these cases give negative Widal reactions later on. There is also a common type of enteritis, with or without blood in the stools, which cannot apparently be attributed to any of the organisms which generally give rise to these conditions. The two stools from which *B. pyocyaneus* (and no other abnormal organism) was isolated were those of mother and child, acutely ill at the same time. A second child died, apparently of the same condition, before the stool could be examined. There is much research yet to be done upon the intestinal bacteria in Samoa.

The only case from which *E. histolytica* was recovered was a sailor, native of Manahiki, who arrived in port suffering from amœbic dysentery. As O'Connor has already reported, this disease is rare or non-existent in Samoans. He only found *E. histolytica* in 9·6 per cent. of 229 stools examined.

Of the five urethral smears in which gonococcus was found, four were from pure-bred Samoan males. It is sometimes said that Samoans are immune; but possibly they are infected more often than we realize; but, if so, they certainly do not suffer from orchitis, strictures, and grave complications which would bring them into hospital.

The Treatment of Yaws (Framboesia tropica) in Western Samoa.

By John S. Armstrong, M.B.,

Resident Medical Officer, Apia.

Historical.

Wilkes, in 1839, describes an eruptive complaint called *ilamea*, which covers many of the children under the age of ten years, and particularly attacks the face and head. He says: "The mode in which it is treated is singular; the child is rubbed with the husks of the coconut until all the scabs are removed; a soft preparation of breadfruit is then applied, after which they are washed." This has

been the Samoan method of treating yaw papules until quite recent times, and may even now be practised in some of the outlying districts. The word *ilamea* was probably used in mistake, as the Samoan uses it only to describe an impetiginous condition of babies. In 1866 Pritchards describes the disease called *tona* (the present Samoan word for yaws) " which attacks the native children almost without exception." Kraemer believes that the disease has long been endemic in Samoa, because the oldest word that the Samoans have for the disease is *patu*, which is the word used in the Sunday Islands for yaws. This would indicate that the Samoans acquired the disease when they were in contact with this race—probably before the time of their migration to the Samoan Islands. On the other hand, Pratt gives the meaning of *patu* as " a fatty tumour," and does not mention it in connection with yaws. Königer believed that the introduction of yaws into the Samoan Islands was quite recent.

In trying to arrive at any decision in this matter two points seem worthy of note:—

(1) That every description of the disease in Samoa states that it is practically a disease of childhood, indicating a long period of endemicity.

(2) The Samoans certainly had an old name of *Lupani* for the disease, which was used before *tona* —the latter word probably came into use during the Tongan wars, the last of which occurred many years before the recorded arrival of Europeans in Samoa, and this is the only authentic record of an early contact of the Samoans with a foreign race.

On the whole, the evidence seems to point to yaws having been long endemic in Samoa, and probably the Samoans brought the disease to these islands or acquired it soon after they arrived.

The Treatment of Yaws in Samoa by European Medicines.

Davies, in 1892, reports that he successfully treated the chronic ulcers of the Samoans. Kraemar, in 1902, used potassium iodide and a local application of salicylate, as he states that he did not like to give mercury to children; but the effect of this treatment was reported successful merely on observations of a single case of secondary yaw rash. In 1910 Poleck stated that he was obtaining cures in twenty days by the use of potassium iodide 0·59 grm. and calomel 0·01 grm. internally, and mercurial ointment for ulcers. The cures by these methods do not appear to have impressed the Samoans, as they continued to favour their own method of treatment. Shortly before the Great War the German doctors started to give injections of arsenical compounds of the salvarsan type. These injections were probably given to only a very small proportion of the population, but were becoming popular amongst the Samoans.

During the military occupation of Samoa by New Zealand troops army doctors were sent round the islands to give novarsenobillon injections whenever it was reported that yaws was prevalent in a district. On these expeditions a single injection was given, and usually no charge was made. This did a great deal to popularize this method of treatment. When the Civil Administration was formed in 1920 these expeditions were continued, but it was noted that the effect of the injections did not last very long in a district. In order to try and make the cures more permanent each case was given three doses instead of one, but, as the cost of the drug was becoming a large item in the medical expenditure, it was decided to try and enforce the payment of fees for the injections. This caused a serious falling off in the number of cases treated. It was then decided to do the children free, but charge the adults the cost of the drug used; but even this led to very little improvement in the number of cases treated.

The desire for this method of treatment played a great part in prompting the support of the Samoans for the passing the Samoan medical tax, which has enabled us to give free treatment. That the passing of this tax has been of great help in combating yaws is shown by the following incidents: Two native officials sent requests that a doctor should be sent to their village to give injections for yaws, as the disease was very bad in the districts. The first official estimated that he had at least one hundred cases; the second did not mention any number. When the doctor arrived he found that there were eleven cases in the first village and twenty-three in the second; and on making inquiries he was told that the others had not come, as they could not pay the fee and were ashamed to ask for free treatment. Eventually a few more were collected and given treatment without charge. Under the system of free treatment at the first visit, eighty-six cases were treated at the first and 117 cases at the second village—and this in spite of the fact that injections were being given at villages every three or four miles, so that the cases in question were drawn from a district with a two-mile radius, instead of five or ten miles, as at the previous visits.

Treatment.—At the present time we give to each case of yaws three doses of novarsenobillon, with an interval of a week between each dose. This is the standard treatment given at all our hospitals and dispensaries (on one or two days a week) all the year round.

To make certain that the treatment is available to the whole population we send parties, consisting of a European doctor and one to three Samoan assistants, round the islands, who stop at every village, or at the central village when there are several within a short distance, and give the injections. On these medical excursions, or " malagas," as they are called, the name, age, village, and dose of each patient is recorded for future reference.

Dose.—The method of administering the drug is to dissolve 0·1 grm. of novarsenobillon in 1·0 c.c. of sterile distilled water, and inject from 0·5 to 6·0 c.c. as a dose, depending on the age and sex of the patient. 0·5 c.c. is given to children under one year that are in poor health, otherwise we start at 1 c.c., and this dose, up to 1·5 c.c., which is given

to children of three to five years, has often to be given into the buttock-muscles. The larger doses are given into the arm-veins with 5·0 c.c. as the maximum female and 6·0 c.c. as the maximum male dose. The same dose is given at each of the three injections.

Method of Administration.—These injections are practically all given by our native medical practitioner and the cadets that we are training to become native medical practitioners. They scrub their hands with soap and water as for a major operation, and then soak them in a solution of biniodide of mercury prior to giving the injections. The dose is given with a 10 c.c. "Record" syringe, and a 2¼ in. fine-bore rustless-metal needle, which are sterilized in carbolic acid, 1 in 20, then rinsed out in sterile water, and the requisite dose drawn into the syringe. The patient's skin over the vein is painted with tincture of iodine by an assistant, and the arm congested by holding a rubber tube round the upper arm tight enough to obliterate the superficial veins without obstructing the arterial flow. The needle is passed into the lumen of the vein, and a little blood is drawn into the syringe to make certain that the point of the needle is free in the vein, then the rubber band is released and the injection given. The syringe and needle are washed in carbolic, 1 in 20, followed by spirit, and the needle is then allowed to soak in spirit or carbolic while the syringe and another needle are rinsed out with sterile water for the next injection. The use of six to twelve needles in rotation allows one operator to give about fifty to sixty injections in an hour.

The intramuscular injection for babies and little children is given at a point midway between the crest of the ilium and the great trochanter of the femur.

On malagas, when distilled water cannot be carried, the water from the village drinking-well or stream is used after having been boiled in a clean kettle and allowed to cool. The drinking water throughout these islands sterilized by this method appears to answer just as distilled water.

Ill Effects from the Injections.—These may be grouped under two headings: (*a*) Immediate, within a few minutes or hours; (*b*) remote, coming on the following day or after.

(*a*) These consist for the most part in vomiting or fainting, with occasional headache. They are almost without exception due to the patient arriving with an overloaded stomach, or having hurried too much coming to the place of injection, with the result that the patient is hot, exhausted and has a rapid pulse. These cases appear to suffer no ill effects if not injected till the pulse is settled down.

(*b*) The remote effects may be classed as:—(1) Skin disturbances, such as erythematous rashes, followed in some cases by desquamation and often associated with a conjunctivitis. (2) Kidney disturbances, which usually take the form of a subacute, but may develop into an acute nephritis. This condition appears to develop much more frequently in the half-caste than with the pure Samoan children and has caused the only case of death that has been reported which could be attributed to the drug. This patient was very ill before the injection was given, so that the death was not entirely due to the drug. (3) Abscess formation: this is by far the most common ill-effect, and usually occurs in the buttock of the poorly-nourished, marasmic babies that are often covered with septic sores; but even under the conditions that are encountered on malaga the proportion of these cases is not high. For example, in the malaga mentioned later, where 1,892 injections were given, only one abscess formed. The buttock-muscles often remain brawny for some days, and in a few cases even weeks, after the injections, and the same may occur in the arm if the novarsenobillon leaks from the vein. (4) *Febrile* reaction; this may last from one to three days, but as a rule causes the patient little discomfort. On the whole the ill effects are very rare, only one case being affected for several hundred injected.

Effect of treatment on Yaws.—In November and December, 1923, to test the effect of this method of treatment, a district was selected whose population was rather isolated, so that the results would not be affected by the arrival of people from other districts. The outlet of this district led to Apia so that any cases that sought injection directly after the malaga would be recorded in the hospital books.

The total population of the district was 2,782, consisting of 1,387 males and 1,395 females. Of the males, 61 were infants under two years, 615 were classed as boys (two to seventeen years), 711 as adult men (over seventeen years); 727 were women over fifteen years of age. Notification was sent to the native officials that the malaga party would give injections at five selected villages—each on a different day—the village being selected so that approximately 500 people lived within easy walking-distance. The injections were given in the early morning of each day, and in the afternoon the party moved on to the village where the next injections were to be given; in this way injections were given every day from Monday till Friday, and on the Saturday the party returned to the other end of the district in readiness to start the second injections on the following Monday morning. This is the method usually adopted on these malagas.

Throughout the district 695 people were injected, consisting of 351 males and 344 females, who received 1,892 injections. The proportion of these cases to the population was slightly less than the average throughout the islands.

During this malaga the type of each patient's lesion was noted, as well as the dose, and any reason for giving less than the normal amount.

In August, 1924, a second malaga was made through the same district, and nearly all the cases were seen that had received injections on the first malaga, and from this source, together with those that had come to the Apia Hospital, it was found that 77 cases had relapsed, comprising 31 females and 46 males.

Colonial Medical Reports.—No. 191.—New Zealand (*contd.*).

Number of cases receiving one injection, 24; relapses, 4=16·6 per cent. Some of these cases did not belong to the district, and had left before the second or third dose was given, so that the proportion of relapses is certain to be inaccurate.

Number of cases receiving two injections, 135; relapses, 20=14·8 per cent.

Number of cases receiving three injections, 536; relapses, 53=10 per cent. Eight of the fifty-three cases received doses that were smaller than our standard dose for age, due to the patient having associated illness, such as mumps.

The cases were divided into the following types: (1) primary sores; (2) generalized secondary papular rash; (3) dermatitis secondary; (4) "crab" tonas; (5) secondary ulceration; (6) gummatous infiltration and ulceration; (7) synovitis; (8) dactylitis; (9) tibial nodes and sabre-blade tibiæ; (10) dermatitis, slaty; (11) plantar and palmar dermatitis; (12) hyperkeratosis.

Primary sores: The proportion of relapses in the few cases treated is very high. This is partly explained by the fact that four out of the six cases were so ill that they received only half the dose that they should have had for their age. Another case was a breast-ulcer on a mother nursing a baby which had the primary sore, and a generalized secondary rash, well-marked round the lips, which was so ill that it could only have a small dose, which did not cure the condition and probably led to the mother being reinfected.

The number of primary and early secondary rashes seen appeared to be so small compared with the numbers in the later stages that at the time of giving the second injection an order was given that all children under two years were to be brought up for inspection. At this inspection only one child was seen that had reached two years of age without being infected, but none was infected under the age of six months.

The reason given by the Samoans for not having brought their young children for the first injection was that they think three crops of frambœsial rash should come out before any treatment is given, and also fear the effects of injecting a young baby. This belief is gradually dying down, but it will probably be some time before the Samoan realizes that his children should come on the first signs of the disease.

The underdosing of the primary cases, although it did not cure the babies, had a marked beneficial effect both on the individual cases and in encouraging the populace to bring their children early, because the cases that we were allowed to inject on the first malaga were so ill that their parents brought them for injection as a last hope, and they all survived and were comparatively healthy, in spite of some secondary rash at the time of the second malaga, which seems to show that the injected children probably derived considerable benefit, although not cured.

Yaws condition commences by the skin on the dorsum of the hands and feet becoming dry and turning a slaty-blue colour. The superficial epidermis is then shed in large, thin flakes, leaving a tight atrophic skin below. This continues for some months, the proximal border gradually spreading up the foot and hand until it reaches well above the wrist and ankle; at the same time all the pigment is extracted from the skin first affected, so that the dorsum of the hand or foot will be leucodermatous, while the ankle and wrist are a slaty-grey. The condition usually starts in the third or fourth decade of life and may continue for many years. In the old-standing cases the process may extend half-way up the leg or fore-arm. On receiving injections, all exfoliation and cracking stop, the slaty colour of the skin disappears, and the whole of the skin becomes more supple and healthy. The leucodermatous patches remain permanently. There seems to be no tendency to recurrence, as is shown by cases that have been injected three years ago without recurrence.

Another condition affects either the soles of the feet or the palms of the hands—usually of adults. Generally the condition shows as a thickening of the skin, which is either punched out in what might be described as worm-eaten holes, or may simply have deep and painful cracks; or the skin may peel off in large, irregular flakes, with occasionally small deep-seated water-blisters in it. The condition is worst in the wet season, and we think that moisture is probably a necessity, if not the only cause, in many of the cases. It shows a great tendency to relapse every year at the same season, and does this in spite of all treatment. The reason for having so many apparent cures was that the first malaga was held in the wet season, while the second was just at the end of the following dry season. The injections seem to always give considerable temporary relief.

In another type there is very marked increase in the horny layers of the skin, usually seen in young adolescents in Samoa. The condition is not common and does not appear to be influenced by the season of the year; we believe that it is probably due to yaws. The effect of N.A.B. injections is variable, but these usually cause considerable improvement.

A large proportion of cases received treatment with potassium iodide as well as injections, but in cases treated medicinally at their homes it is always uncertain whether the medicines prescribed are taken as directed or even whether they are taken at all, so that no more mention will be made of this additional treatment.

The percentage of relapses in the earlier stages of the disease is much greater after only two doses than after three doses of novarsenobillon, and probably four injections would give still better results; but there is always the danger that if we make the cure too complete we may remove the immunity that an attack of the disease conveys against a second infection.

At the present time some 54,000 injections have been given on the three-injection system without causing a single case to become reinfected with yaws.

so that it may be fairly safely assumed that we are not removing the immunity conveyed by an attack of the disease. If the cases were completely cured and all immunity lost, it would seriously affect our campaign, for at present the primary and secondary stages of the disease are entirely confined to the children amongst the Samoans, and a cure that allowed of reinfection of adults would soon tend to lose favour, however good it might be, for large areas of the population can receive treatment for the condition only once or twice in the year at the most. When the medical service has expanded sufficiently to allow us to have native medical practitioners in every district of Samoa, so that cases can receive immediate treatment, then complete cure will be safe and will be the ideal treatment. But at the present time we endeavour to keep an immune adult population, by merely treating cases sufficiently to cure the infective primary and secondary rashes which may also prevent the occurrence of the disabling tertiary conditions. This, we hope, will allow a large proportion of the present children to reach adult life without becoming infected, and so gradually exterminate the disease without risking a serious epidemic of yaws amongst the adult population before we have the personnel to control it.

The immunity which an attack of yaws gives the Samoans in preventing their infection with syphilis, as stated by Parham, seems to be very great, as we have never seen a case of syphilis in a Samoan; and we think that it would be a crime to remove that immunity at the present time. By the time that the present children reach adolescence it is hoped that syphilis will have very largely been brought under control by the European races, so that the chance of its introduction will be very much less, and, even if introduced, the population will be under more close medical supervision, so that any outbreak would be quickly reported and controlled.

Conclusions.

1. That in the treatment of yaws, with a view to eradicating the disease, some system of free injections for the patients is essential.

2. That the system of three injections, which we practise, does not entirely destroy the immunity conferred by an attack of yaws.

3. That at present it is desirable to maintain a certain amount of immunity in the population of Samoa to prevent the introduction of syphilis.

4. That the system of three injections prevents a large amount of the sickness and disability in the Samoan population from yaws, although a small proportion of the cases still relapse, but this is preferable to a more thorough treatment which might remove the patients' immunity and allow of reinfection.

5. That Samoans can readily be trained to administer this treatment, and it has proved to be a safe remedy in their hands.

The Control of Mosquitoes in Apia, Samoa.

By P. A. Buxton, M.R.C.S., L.R.C.P., D.T.M.&H.

(*Expedition of the London School of Hygiene and Tropical Medicine to Samoa*).

I propose to record some observations upon the mosquito (*Ædes variegatus*, *Stegomyia pseudoscutellaris*) which carries filariasis in Samoa, and to confine myself rather strictly to what has obvious bearing on the question of reducing the numbers of this very dangerous insect. But before I discuss the specific measures for its control it must be understood that no work directed against this one species will be effective unless general anti-mosquito measures are also prosecuted vigorously. The success of any health campaign depends largely on the interest and help of the mass of the population.

The most irritating mosquito is not the day-biting *Stegomyia*, which is our special objective, but the virulent night-biting *Culex fatigans* and *Finlaya kochi*. As long as the *Culex* and *Finlaya* make night unpleasant, so long will people in general say that anti-mosquito measures are useless and irksome, even if a great reduction in the numbers of the more dangerous *Stegomyia* is effected. The principal breeding-place of *Culex fatigans* in Apia appears to be septic tanks and pit privies. It would be a very simple matter to screen with gauze the ventilators of the septic tanks; it would not be an enormous task to treat the pit privies with creosol once a month. The extermination of *Finlaya* is a simple matter, though I doubt if public opinion is ready for it; it can be accomplished by forbidding the growing of taro and tamu (*Colocasia* species) within the municipal area. This measure would be entirely successful, and no other measure would be the least use. Every taro plant holds a few ounces of water among the bases of the great leaves, and in every plant one can find the larvæ of *Finlaya*, and this is their only regular breeding-place. It would greatly assist in reducing the amount of taro grown if the water-level of the Taufusi Swamp could be lowered a couple of feet. Speaking as an amateur, I feel hopeful that the control of the mouth of the Mulivai by gates which could be shut at high tide would effect a great deal at small cost. The urgent need of dealing with this swamp must be apparent to anyone who gives attention to the matter. It occupies land which must be used as a town site, and which will greatly increase in value as agricultural land when it is drained; it makes the proper disposal of sewage almost impossible; above all else, it is a great potential danger, because if *Anopheles* were introduced from the New Hebrides or Solomon Islands, Samoa would be faced by such an epidemic as decimated Mauritius in 1867-68. The evidence tends to show that two species of *Anopheles* were introduced into Mauritius from Africa, over a much greater stretch of sea than that which separates Samoa from Melanesia; the result was the ruin of Port Louis and the coast zone, the emigration of the white population to

the hills, and the death of over thirty-two thousand people in two years. Once the Taufusi Swamp is drained, the accidental introduction of *Anopheles* will be less likely.

So much for the more general mosquito control, which will render life more pleasant, but which will not effectively reduce the numbers of any disease-carrier. Let us turn to the question of controlling the carrier of filariasis, *Ædes variegatus* (*Stegomyia pseudoscutellaris*), remembering that a large proportion of natives (O'Connor found a filarial incidence of 58·3 per cent. in 2,509 Samoans over fifteen years) are infected by it and suffer from the diseases associated with its presence in the body. The habits of this particular species of mosquito have already been studied by Doane and more recently by O'Connor. Since our arrival in Apia in January, 1924, my assistant, Mr. G. H. E. Hopkins, and myself have devoted a good deal of time studying its natural breeding-places, but we have done little more than confirm the findings of the earlier workers. The principal breeding-places are:—

(1) Coconut shells, both those which have been opened by man in cutting copra or for drinking, and also fallen green nuts opened by crabs and rats.

(2) Rot-holes in trees. The insect is by no means a domestic insect, and great numbers may be found in every uncultivated part of the island. The commonest rot-holes in town are those in kapok, candle-nut, fao (*Hibiscus tiliaceus*) and other trees which are pollarded and used as fence-posts. Breadfruit-trees are dangerous because horses gnaw the bark and let in the rot. Mangoes are dangerous because their great forks often hold several gallons of water. The steps cut in the trunks of coconut-palms often contain water and larvæ. The mangroves (*Rhizophora*) in the mouths of the rivers are full of little holes in which *Stegomyia* breeds in great numbers. This is quite a serious matter in Sogi and the west end of Apia generally.

(3) Cacao-pods, gnawed by rats, are an important breeding-place, but hardly matter in Apia, as so little cacao is grown close to the town.

(4) There are a number of breeding-places of less importance—holes in rocks (especially when full of rotten leaves) water-buts, old tins, &c. I have no evidence against the crab-holes on Mulin'u, and I have not yet found larvæ in the crown of coconut-palms.

After studying the mosquitoes for several months, I arranged with the chief medical officer to attempt the practical control of this insect in that part of the town between the Mulivai and the Vaisigano. The inhabitants are mostly white or half-caste, and were very willing to do their part, and the work was carried on as a large-scale experiment for six months. I reached the following definite conclusions:—

(1) *Ædes variegatus* was certainly greatly reduced in numbers.

(2) Health inspectors could very easily carry on the work, but they must be specially trained. It is not sufficient to look for unscreened cisterns, sagging gutters, old tin cans, and obvious breeding-places of that sort. One must search also for rot-holes, even little ones, and either drain them with a chopper or else fill them with stones and sand. One must also pay special attention to the clearing of scrub in paddocks, &c., around gardens. It is only when it is cleared that the coconut-shells become apparent and can be collected and destroyed. By clearing scrub the general ventilation of houses is also enormously improved and the collection of the copra is facilitated. By attending to rot-holes and the cutting of scrub a very great reduction in the numbers of this mosquito may easily be maintained.

It is quite impossible in the present state of knowledge to exterminate this insect, because the great forest areas, with their innumerable little rot-holes, are its stronghold. Any method, therefore, which can be used to reduce the numbers, even a little, is valuable. I propose to search in the New Hebrides for insects which might possibly prey on the larvæ of *Stegomyia* and be capable of breeding in the little rot-holes, &c., in which they are found. If such a predaceous insect could be found, and if it was not objectionable on other grounds, it would constantly be doing its bit, and doing it at no cost to the community.

(4) Public Health Regulation No. 5 is sufficiently clear and wide; I only made formal use of it on two occasions. If at any time it is revised it might be well (*a*) to include "rot-holes in trees" among the breeding-places listed in paragraph 4, and (*b*) to forbid growing taro and tamu within the Apia municipal area—if the time is ripe for doing so. It will also be necessary to take steps to cut mangroves regularly as often as they are big enough to have rot-holes in them. This would have to be done by the Government. There is presumably no responsible owner of a tidal mangrove swamp.

The Clayton Lane Technique used in the Field to Control Hookworm Treatment.[1]

By G. H. E. Hopkins, B.A., F.E.S.

(*Expedition to Samoa of the London School of Hygiene and Tropical Medicine.*)

The author was recently requested by the Administration of Western Samoa to carry out an investigation into the efficacy of the treatment now in use against hookworm infection among the native population. The experiments described below were made in fulfilment of this request. The results are thought worthy of publication because the Clayton-Lane technique has apparently not often been used in field work, and the much-used Willis technique is here directly compared with it. The form of the method used was that described by Colonel Lane ("The Mass Diagnosis of Anky-

[1] Reprinted from *Trans. Roy. Soc. Trop. Med. and Hyg.*

lostome Infestation," *Trans. Roy. Soc. Trop. Med. and Hyg.*, March, 1924), who instructed the author in the technique. It was therefore exactly as used by him. Colonel Lane also passed the apparatus used as being correct. It was made by Messrs. R. B. Turner and Co.

A series of fifty-four specimens from individuals taken at random from the patients and staff in the Apia Hospital, Samoa, was examined in order to compare the accuracy of the Clayton-Lane and Willis techniques. A number of these stools were also examined by the direct smear method. The Willis method is as follows: About a gramme of fæces is well mixed with saturated salt solution in the quarter-ounce tin container in which it is obtained from the patient. The tin is then filled to the brim with the salt solution and a glass slide is placed over it. After about twenty minutes the slide is removed and examined under the microscope, smear side up. Malakai, a Fijian assistant of Dr. S. M. Lambert, of the International Health Board of the Rockefeller Foundation, performed the examination by the Willis method, while those of the Clayton-Lane method was performed by the author. Malakai was expert in the Willis technique, having used it in working under Dr. Lambert for a considerable period.

Of the fifty-four individuals examined, the Clayton-Lane method showed fifty (92·6 per cent.) to be infected, while by the Willis method the number found affected was forty-seven (87 per cent.). From seven individuals who were lightly infected several specimens (nineteen in all) were examined by both methods on different days. Of these nineteen specimens the Clayton-Lane method showed fourteen (seven individuals) positive for hookworm while the Willis method showed only four specimens (three individuals) positive. It is evident that for very light infections the Clayton-Lane technique is much more accurate than that of Willis. One of the cases in which the Clayton-Lane method gave a positive result while that of the Willis method did not was that of Malakai himself. He was convinced that this was an error, possibly due to the carrying-over of an egg in the cylinder used for measuring the specimen of fæces, and to prove himself free from infection he took 3 c.c. of oil of chenopodium on his return to Fiji. The result was to demonstrate the accuracy of the Clayton-Lane method, for in his first day's stools he passed one male and one female *Necator americanus*.

On completion of this preliminary work the author examined a long series of Samoans living in Aleipata, a district at some distance from Apia.

The district was chosen because it had never received mass hookworm treatment. The population is a fair average example of Samoans living under normal conditions and not much in contact with Europeans. There are drop latrines over the sea in some of the villages, but the seashore and bush round the village are favourite places for defæcation. Furthermore, the taro patches are at a distance of some miles from the villages, and the soil in their neighbourhood must be heavily polluted. The cases were collected at random, except that no children apparently under twelve years of age and no persons who had previously had hookworm treatment were accepted. The procedure was as follows:—

Containers (the quarter-ounce tins used by the International Health Board in the Willis technique) were given out to the people through the head man of the village, and brought in by the individuals themselves next day. The number of eggs obtained from 1 c.c. of fæces from each individual by the Clayton-Lane method was counted, and each person was treated with a mixture of oil of chenopodium (one part) and carbon tetrachloride (three parts), the dose varying according to the age and health of the individual, but with a maximum of thirty-five minims of the mixture, given in an ounce of magnesium-sulphate solution (one part salts in four of water). After an interval of three weeks a second specimen was examined in the same way, and a second dose of the drug administered to each person. A third examination at the end of a further three weeks gave the result of this second dose. No complaints of ill-effects from the drug were received, and several patients stated spontaneously that they were much benefited by the treatment. The preparation of the stools for examination was done by a Samoan medical cadet, who performed the work quite satisfactorily after doing it under supervision two or three times. It was found that a trained microscopist can without difficulty count the eggs in about ten or twelve samples of fæces per hour, but this number varies considerably with the average severity of infection, specimens containing many ova taking much longer to count than those containing few (the heaviest infection found was 1,050 eggs per cubic centimetre of stool).

The specimens were centrifuged two at a time, and it was found that the centrifuger was able to keep the microscopist constantly supplied on the first examination, but not on the later ones when the average infection was lighter.

If a mere diagnosis of positive or negative were required a much larger number of specimens could be examined in the same time and a centrifuge with a larger number of buckets would be desirable. The apparatus is quite light, and could easily be carried from one village to another by one man. The only piece of apparatus required locally is a table on which to fix the centrifuge. Failing this a substitute can easily be improvised. Apart from the preliminary cost of the apparatus, the method is very economical, the only material required being a saturated solution of common salt. The counting of eggs in a heavily-infected specimen would be much facilitated by the use of an eye-piece micrometer ruled in 1 mm. squares. A drawback of the technique is that the salt solution used rapidly corrodes the aluminium arms of the centrifuge. This could probably be avoided by giving the arms a thick coat of paint or varnish or (better) using arms made of brass or some other metal not affected by salt.

Colonial Medical Reports.—No. 191.—New Zealand (*contd.*).

The results of these examinations are shown in the following table. Since Clayton-Lane does not claim that his method is accurate for ova of *Ascaris*, no special search was made for these, but a note was made when they were observed. The figures of ascaris infection are therefore only approximate.

In the columns headed "Total eggs" and "Average number of eggs per cubic centimetre per person," those individuals who did not come up for all three examinations are ignored. It will be seen from the table that the number of total cures resulting from one treatment was not very great, the percentage of infected persons being reduced to a little less than two-thirds of the previous figure. The reduction in the number of eggs, and therefore of a number of worms per individual was, however, very striking, in spite of the fact that in a few cases no change or even increase was observed. Such cases are probably accounted for by migration of hookworms from the lungs to the gut during the three weeks' interval, though it is possible that some were due to substitution of a specimen from a different individual before it was brought to the laboratory, since it was not practicable to actually supervise the filling of the tins. Every precaution was taken to avoid the sharing-out of one stool amongst several persons, and such points as the colour and consistency of the stool and the presence and severity of *Ascaris* infection were a useful check in doubtful cases. Such sharing-out was detected in one case, but it probably did not take place to a degree sufficient to vitiate the results.

	Hookworm			Ascaris		
	Number examined	Number infected	Infection percentage	Total eggs (294 persons)	Average number of eggs per cubic centimetre per person	Number infected	Infection percentage
Before treatment	333	322	96·7	21,108	71·8	113	33·9
After first treatment	309	183	59·2	3,201	10 9	22	7·1
After second treatment	294	110	37·4	585	0·2	26	8·8

The results of the third examination correspond well with those of the second, the percentage of infection being again reduced by about one-third, while the average number of eggs per specimen was very greatly reduced.

It would appear that while the effect of one treatment is very good, it is desirable that it should be followed by a second. It is doubtful if, under conditions of mass treatment, a third dose is desirable. It also appears that the Clayton-Lane technique can be usefully employed in the field to diagnose the residual infections after treatment has been given. For this purpose the Willis method is quite unsuitable, owing to its inaccuracy in the case of light infections.

Health Survey of Western Samoa, with Special Reference to Hookworm Infection.

By S. M. Lambert, M.O.,

Of the International Health Board of the Rockefeller Foundation.

Transmissible Diseases.

There is a list of thirty-three transmissible diseases which are notifiable: Anthrax, cerebro-spinal fever, cholera, dengue, diphtheria, erysipelas, enteric fever (typhoid and paratyphoid), leprosy, plague, puerperal fever, small-pox, typhus, scarlet fever, yellow fever, chicken-pox, encephalitis lethargica, influenza, measles, German measles, mumps, ophthalmia neonatorum, acute primary pneumonia, acute poliomyelitis, ringworm (scalp), scabies, trachoma, tuberculosis, tetanus, whooping-cough, dysentery, venereal disease, yaws, beriberi. The prevalent diseases are frambœsia (or yaws), hookworm disease, ascariasis, filariasis, bacillary dysentery, measles, chicken-pox, mumps, lobar pneumonia, tuberculosis, leprosy. Skin diseases, such as tinea imbricata and itch, and eye diseases are also very common. The Samoans have their own herbal remedies for these diseases, and use massage very largely for the relief of pain.

Frambœsia, or Yaws.—This disease occurs in every village, and so prevalent was it that one might say that hardly a single Samoan reached adult life without having suffered from the infection.

Hookworm Disease.—This will be discussed in a later section.

Ascariasis.—In children ascariasis is very common, and is the cause of a considerable mortality to the younger children, producing two types of illness, a form of broncho-pneumonia and an intestinal type, which has high fever, and then suddenly the patients go into convulsions or collapse and die—very much like a case of acute enteritis. In adults the worm does not appear to cause much disability.

Filariasis.—This disease is very widely spread through the islands. The most frequent clinical manifestations of the disease are lymphadenitis, with or without lymphangitis; filarial abscesses; while a certain proportion of cases develop elephantoid swellings of the limbs, and pudenda, and breasts in females. The large incidence of hydrocele amongst the natives is probably due to filaria worm. The microfilaria appear in the blood of the peripheral circulation at all times during the twenty-four hours, and of the six species of mosquito in Samoa, Dr. F. W. O'Connor was only able to incriminate one—*Stegomyia pseudoscutellaris*—as the intermediate host. This mosquito

bites at any time of the day or night, but is most active about sunset. An expedition under Dr. P. N. Buxton, from the London School of Tropical Medicine, will spend two years on the study of the prevention of filariasis in Samoa.

Bacillary Dysentery.—This disease is endemic in the islands, and occasionally gives rise to small epidemics, which tend to be fatal to the children, but do not cause much mortality to the adults. A small epidemic in 1923 was due to an organism of the Shiga group. Amœbic dysentery, if it exists among the Samoans, must be very rare, but there is an occasional case from the Chinese labourers, so that there is always the chance of its spreading throughout Samoa.

Measles.—This disease is probably endemic in Samoa, and recurs a mild epidemic form about every four years; on the whole the disease runs a mild course and has very few complications.

Chicken-pox.—Sporadic cases occur all through Samoa, and cause very little disturbance to the patient.

Mumps.—This disease is quite common amongst children of four to twelve years, and nearly always affects only the parotid glands; there are no records of any complications, and the disease does not appear to involve the genital organs of the male or the breasts of the female children. The inflammation of the glands is so slight that there is rarely any appreciable difficulty in opening the mouth.

Lobar Pneumonia.—This disease is very common in certain seasons of the year, and practically always seems to pick out the basal lobes. Cases treated in hospital do extremely well, the mortality being very low.

Tuberculosis.—Bone and joint tuberculosis is very rare amongst Samoans, if it exists at all Tuberculosis of the lungs is very common, and a fatal disease to the natives, and still more so the half-caste population, whose houses are often poorly lighted and badly ventilated. Amongst the Samoans there are lung infections which cause hæmoptosis and to some extent simulate phthisis, but no acid-fast bacilli can be obtained, and from their complete recovery after the case had been considered from a clinical point of view as hopeless, we think that they are probably due to another infective agent, possibly "bronchial spirochætosis," as spirochætes have been found in spare numbers in the sputa of some of these cases. In children tubercular peritonitis often associated with phthisis is fairly common, as also is tubercular meningitis.

Leprosy.—The first cases ever diagnosed as leprosy were diagnosed in 1892; these were two Chinese. The next cases appeared in 1896, and were in people who had come from Hawaii. So far as is known there was no leprosy known in Western Samoa previously, and from the evidence available it is reasonable to conclude that the disease was introduced from Hawaii. Altogether there have been only forty-six cases to date recorded, of whom twenty-three are Samoans. At the present time the administration is supporting sixteen lepers at Makogai, in Fiji. New cases as discovered are sent to Fiji once each year.

Itch.—Scabies is fairly common amongst the children of Samoa, and occasionally it is seen in cases suffering from some chronic ailment who have been neglected by their friends and relatives; but on the whole the adult population is very little affected.

Tinea Imbricata.—This and other ringworms are fairly common amongst the Samoans, but the incidence is not nearly as great as it is amongst the Melanesian and Chinese labourers employed on the plantations.

Eye Diseases.—Simple catarrhal conjunctivitis is common, but the most serious condition is the true Samoan conjunctivitis, which is very infectious, and spreads rapidly from village to village, beginning with itching, swelling, and marked chemosis of the palpebral conjunctiva, which, within forty-eight hours has a purulent discharge, associated with great pain and photophobia. The inflammation soon spreads down the naso-pharynx having involved both eyes. In default of proper treatment, ulceration of the cornea follows, and then, if the native treatment of scrubbing with coco-nut fibre is adopted, the destruction of the eye-ball is a very probable result, and is the reason of there being so many cases of blindness in Samoa. Clinically, the condition resembles gonorrhœal ophthalmia, except that there is very little constitutional disturbance. An intracellular Gram-negative diplococcus is very constantly found in the discharge. It is very noticeable that villages near a bathing-beach, or which have adequate bathing facilities, show few eye diseases. As soon as one leaves the beach, or where there are few bathing facilities, eye diseases become much more prevalent.

Venereal Diseases.—Syphilis, which has been reported from time to time amongst the Samoans is probably very rare, if it exists at all; the cases that have been reported having turned out to be a yaws condition. The Chinese coolies have a small percentage of syphilitic cases, but there appears to be no evidence of their having passed the infection on to the Samoans. Gonorrhœa of a very mild type seems to be fairly common, but gives disabilities to few, as it does not cause retention of urine in the male or stricture, while no cases of salpingitis of diplococcal origin have been seen in the female. The Gram-negative diplococcus, which causes the urethritis, may be the same organism that causes the Samoan conjunctivitis, but Dr. F. W. O'Connor, when working in Apia, found that it was the exception to find any organism in the urethra in the cases of conjunctivitis which would lead one to expect that the conjunctivitis is spread directly from one person to the next, or carried by numerous flies, which are very persistent in their endeavours to alight on the eyelids.

Mortality in Samoa.

In 1923 the births of 1,701 living children (Samoan) were registered in Western Samoa. The number of live births in 1923 is the second highest

recorded, the highest being 1,792 in 1912, with a population of 24,239. Stillbirths, of which twenty-one are recorded, are not included either as births or deaths.

The number of deaths registered during the year was 1,398. The increase was due to an epidemic of dysentery. The crude death-rate was 41·5 per thousand of mean population. Of the 1,398 deaths, 719 were of children who had not reached the age of two years. Nine women died in childbirth.

Yaws and Hookworm Control.

1. *History of Hookworm Disease in Samoa.*

In 1920 Dr. F. W. O'Connor, of the London School of Tropical Medicine, carried out a preliminary survey which showed that hookworm infection among the Samoans was almost universal. He reported that he found an infection rate of 85·1 in 286 examined, but this was in some cases from one specimen only, and that among those examined for filaria the eggs of hookworm were eventually always forthcoming. The largest number of worms found by him was 113.

Hookworm Control.

The institution of free treatment in April, 1923, made it possible to commence a systematic campaign against the disease. The campaign was based on the International Health Board model, which had been studied in Queensland and Fiji, and with films, lantern slides and charts purchased from them a commencement was made to educate the native to the necessity for treatment and for better sanitation. This continued till October, by which time 18,057 mass treatments had been given. The work went slowly at first. This was probably due to lack of confidence on the part of the natives, who still had a vivid recollection of the havoc wrought by the introduction, during military occupation, of influenza in 1918, in which many thousands of lives were lost. In the first three districts treated, with a population of 7,924, only 4,526 offered themselves for treatment, a percentage of 57; in the next five districts, with a population of 14,444, they became more alive to the value of the treatment, and there was no difficulty in treating 13,004, or 90 per cent.; 925 other people were treated in hospitals. These were all treated with carbon tetrachloride, two minims to the year to the apparent age of fifteen, when the adult dose of 45 minims was given. At first this dose was given followed by a purge of magnesium sulphate in two hours. Later the drug was administered in saturated solution of magnesium sulphate.

By October, 1923, the pressure of the natives on the medical staff for the free treatment of yaws became so great that the hookworm campaign had to be temporarily abandoned for the lack of personnel to handle the two pieces of work. At the beginning of the year the natives had agreed to an additional tax of £1 per head of adult males for free medical attention, and the treatment of yaws with its spectacular results appealed to them more than the hookworm work. Their views had to be heard to assure the successful collection of the first tax, and to gain their firm support to the medical department.

Dr. O'Connor found 35 per cent. of ascaris infection. Future treatments will be given of 25 per cent. of oil of chenopodium to 75 per cent. of tetrachloride to handle this infection as well. The dosage will be two minims to the year, with a maximum of thirty-five minims.

3. *Yaws Campaign.*

The conditions which led to the inauguration of the yaws campaign have been mentioned above. Yaws is probably the greatest cause, direct and indirect, of death among the Pacific races in the first two years of life. Its tertiary effects are the cause of much suffering and ill-health throughout adult life. The treatment of this condition in Pacific islanders is probably the finest demonstration to them of the value of western medicine. During 1923 the demand for injections was so great that treatment was given to all offering themselves; no attempt could be made to fine-comb the whole population. The result of the year's work appealed to the natives so much that the native Parliament of Faipules, or chiefs, agreed to the introduction of very stringent regulations for the control of this disease.

"Regulations in Respect of Yaws."

"Whereas yaws is a preventable disease very common in Western Samoa, responsible for much suffering and death; and whereas the Administration of Western Samoa is spending large sums of money in an endeavour to eradicate this disease; and whereas the co-operation of the Samoans is essential to the successful issue of this work:

"Now, therefore, these regulations are made by the Administration of Western Samoa in pursuance of the Samoa Act, 1921.

"(1) These regulations may be cited as the Samoa Yaws Control Regulations, 1924.

"(2) As from the 1st day of April, 1924, the disease known as yaws shall be a notifiable disease.

"(3) The father or the mother of any child suffering from yaws shall immediately report the sickness to the Pulenuu of the village.

"(4) The Pulenuu of each village shall immediately report all cases of yaws coming under his notice to the Resident Commissioner, Savai'i, or the Secretary of Native Affairs, Apia.

"(5) No child suffering from yaws shall be allowed to travel from its village to any other village, except for the purpose of being treated by a doctor.

"(5) No child suffering from yaws shall be allowed to enter or to remain in any other village than the one in which it usually lives, unless for the purpose of visiting a doctor.

"(7) The Samoan methods of treating yaws are hereby strictly forbidden.

"(8) Every child under the age of ten years shall be produced for inspection by a medical officer when required.

"(9) The parents of every child brought to a medical officer for treatment for yaws shall see that the child undergoes the full course of treatment prescribed by the medical officer.

"(10) No parent shall refuse to allow treatment to be given to any child suffering from yaws when a doctor is in the district.

"(11) Any person refusing or neglecting to obey the provisions of these regulations shall be liable to a penalty of £1 for every such offence."

During the first year of the campaign 32,336 injections were given. The work was recommenced in April, 1924, and during the four months ending July 30 12,000 treatments were given. The whole of Samoa will have been completed by the middle of October, when the hookworm campaign will be recommenced.

A yaws unit consists of a European doctor with two or three native assistants. They take out a supply of a few thousand doses of novarsenobillon, a sufficient quantity of distilled water, syringes, and a sterilizing outfit. The dose given is 0·6 grm. for an adult male and 0·5 for an adult female, and children in proportion. An area which will occupy a unit for five treatment days is selected. On the first round the doctor examines all cases offering themselves for treatment, selecting those showing any signs or symptoms of yaws, and gives them their first injection, making a careful list of the name and village. Saturday is spent in retracing his steps to the starting point of the week. The second and third weeks are spent in giving second and third injections to those previously treated. On the second and third occasions the treatments diminish in number, as the first injections in many cases clear up the obvious lesions and the native can see no reason for further treatment. The matter of more than one treatment was not pressed in the first round of Samoa, as the campaign was intended to be one of education as much as one of treatment. With the new regulations a complete course of three injections is being insisted upon. On the first round it took fifteen months to complete the whole population. The second round, with the improvement shown by the first treatments, will be completed in six months. In treating the whole population it was found that the average dose given was 0·45 grm. On the first round many young children were not brought forward, as the Samoan considered that the injection would only "drive in the disease." On the second round it is found that parents bring their children forward freely.

4. *Present Hookworm Survey.*

This work was rather limited in Samoa because of the short stay occupied by the trips of inspection, also by the fact that Dr. Buxton, of the London School of Tropical Medicine, had planned to make such surveys a part of his programme.

We had the opportunity of seeing the new Clayton-Lane method of diagnosing hookworm ova. Briefly, a definite amount of fæces, about 1 grm., is measured by a small metal ring grasped by long-handled forceps, and pressed repeatedly into different portions of the specimen. This, ring and all, is dropped into a centrifuge tube, gently shaken with water, the ring is removed, and the tube centrifuged a thousand times a minute for one minute. The water is decanted. The tube is refilled with saturated sodium-chloride solution to the very top, and is covered with a small, thick glass slide, which fits between four horns added to the ordinary container of the centrifuge tube. The centrifuge tube is ground to make close union with the glass slide. This is then centrifuged a thousand times a minute for one minute. The slide is then lifted from the tube and suspended drop downward on two plasticine pillars placed on a larger slide which is in the grasp of the mechanical stage. The eggs are thus usually seen in a clear medium lying close to the glass slide in one even plane. It is the most beautiful demonstration of hookworm ova that I have seen. Clayton-Lane has shown that the eggs left after the first slide are almost negligible. The smallest infection can be shown by this method, an excellent one for measuring the reduction of hookworm infection of a population in eggs per gramme after mass treatment. The only objection to this would be the difficulty of counting the masses of eggs in the small area in case of heavy infection. Another objection to this method for field work is that it is unreliable in diagnosing ascaris infection, which has become an important part of hookworm campaigns in many districts, and is unreliable for trichuris eggs. These do not seem to cling to the drop that is brought away by the glass slide after centrifuging, as they do in the Willis method of salt flotation in the usual container. Just what percentage of accuracy is obtained by the Willis method in the case of ascaris it would be interesting to know, but this is quite certain, that it is far more accurate than the direct smear and centrifuge method, or than the Clayton-Lane apparatus.

Having the opportunity, I was anxious to try the ordinary field technique of the Willis method against the accurate Clayton-Lane method of direct centrifuge flotation, to learn what our percentage of error in field work might be. I had with me Malakai, a native of Fiji, trained to the microscopic examination of fæces. While I was absent in Savai'i he ran a set of tests, using the ordinary field technique, even to the quarter-ounce containers for specimen. The plan adopted was that Malakai examined persons by this method, which is the Willis technique. A small portion of fæces, about 1 grm., is well mixed with saturated salt solution in a quarter-ounce container in which it is obtained from the patient. The container is then filled with the solution, and over it a glass slide is placed for twenty minutes or more, when it is lifted from the tin and placed under the microscope, smear side up. The eggs are found floating in the salt solution, which adheres to the slide.

Colonial Medical Reports.—No. 191.—New Zealand (*contd.*).

Each specimen examined by Malakai was usually examined by direct smear by a European assistant of Dr. Buxton. When Malakai's specimen was found negative the Clayton Lane apparatus was used by Mr. Hopkins to confirm it.

The only Fijian examined was Malakai, my assistant, who was sure, after his own examinations, that he had no hookworms. On the first examination the Lane method and the Willis method found him negative. On the second day Willis found him negative and Lane found one egg. Malakai was a little indignant, and on return to Fiji insisted on 3 c.c. of oil of chenopodium to prove his microscopy correct, thinking that the one egg of the Lane method was an added infection carried in by the long forceps carrying the ring of fæces. However, a very minute examination of two days' stools found one female and one male necator passed in the first twenty-four hours' motions. This seems to me a rather brilliant demonstration of the accuracy of the Clayton Lane method. In seven cases specimens were repeated to the number of nineteen specimens. In five of these seven cases Clayton Lane found a negative and a positive. In three of these cases Willis found a negative and a positive. It seems to me fair to say that where Clayton Lane finds a negative and positive in the same case the worm content is probably one female. And it seems to me fair to conclude also that the Willis technique is accurate down to the question of a female worm or two as done under ordinarily careful field conditions.

Fifty-four individuals were examined for hookworm ova by the Clayton Lane and by the Willis techniques. Clayton Lane and direct smear found fifty positives, and Willis found forty-seven positives, respective percentages of 92·6 and 87.

Where the question of hookworm ova alone is concerned, and it seems desirable to show the last one of these, Clayton Lane shows a beautiful accuracy. The Willis technique is accurate down to a worm or two.

I am told that the Lane method makes no claim to demonstrate accurately ascaris or trichuris ova, nor did it in Apia The Willis method does so more accurately than any other method of which I know.

In the South Seas specimens have to be examined within twenty-four hours or flotation methods are useless. Refrigeration is out of the question, and no proper method of keeping specimens for a period that lends itself to ready examination has yet been devised. The Clayton Lane method cannot be operated accurately by the average native assistant, in my opinion, nor can it be used to advantage away from mixed centres. The Willis method can be used anywhere, and the stupidest assistant cannot hinder its accuracy. The Willis method is several times more rapid than the Clayton Lane method, and infinitely more economical.

In selected areas Clayton Lane technique might prove valuable in checking the results of field treatments. The Willis method is the desirable one for field use where rates of infection are desired for decision as to mass treatments, and time and expense are objects, and where information is sought as to infections other than hookworm.

5. *Hookworms Recovered.*

Several individuals were treated and their worms recovered. The conditions were such that no opinion could be formed as to effects of dosage. One hundred and sixty-three hookworms were recovered, of which 161 were necators and two were ankylostomes. Some of those treated were Chinamen. The intestines of two pigs were washed and their worms recovered. There were no human hookworms among these. These worms have all been forwarded to Dr. S. T. Darling for more careful survey.

Discussion and Conclusions.

Discussion.

The average white man sits in the shade in the South Seas and talks of the lazy native, and criticizes Government for not compelling (always the same word) the native to do this thing or that which will benefit him (the white man), with never a thought for the native himself. In the first place, the native is not lazy when he is interested nor when he wants to hold a job. Where nature is so bountiful and the necessities of life are so easily obtained as in most Pacific islands, natives do not seek hard work any more than whites would under the same circumstances; but where conditions are more difficult, as they are in many districts, then the native has to work as hard as any white man. In Savai'i some villagers have their gardens at a distance of miles, and must carry in their produce on their shoulders. In many parts of Fiji and other islands natives have to work and will work at hard labour to support their families.

Every colony in the Pacific faces the problem of a decreasing native population in the face of a need for an increasing labour supply to develop these islands for their products, which have grown to be necessities of the food supply of the temperate civilizations.

The causes of the decrease of the population are, broadly, decay of custom and introduced diseases—both due to the entering of white civilizations.

The easy answer is the importation of Asiatics. This is undesirable for political reasons, and in almost all cases it will finally produce a problem more difficult than the present one. And they mean the earlier extinction of the Native races. The true answer to this problem, and the far-sighted one, is the care of the health of these peoples and their protection from new epidemics while we are ridding them of the effects of those already introduced and to which they have little immunity, as well as ridding them of two or more diseases which have been prevalent among them

for an indefinite period. We must gain their confidence and trust in Western medicine and civilization. We must instil new ideas and ideals of daily life to take the place of such old customs as are incompatible with their new life. The result of such an effort will be the large increase of the population and the final pressure of that population on the means of subsistence will furnish labour for the development of the islands in an increasing amount. The birth-rate among them is so large under normal conditions that with a death-rate lowered by preventive medicine population figures will soon show a large enough increase to produce plenty of surplus labour for white plantations or necessitate an enlargement of their plantations by the natives, with increased exports and imports for the country. Samoa is well along on the road to this happy condition with her increasing population of healthy, contented natives.

Conclusions.

In Samoa we have a long-visioned Administration which is giving every support to a strong native department and a modern department of public health, these two working hand-in-hand. Yaws is well under control, and may be eradicated in the near future. Hookworm control measures are well advanced, and will now be prosecuted with the vigour given to the yaws campaign. Adequate sanitation, proper latrines, and pure water supply are gradually being installed in all villages. Definite plans are undertaken for child welfare work in native villages with the new year.

Even thus early, these measures are being reflected in increasing populations of healthy, happy Samoans. A few years and they will mean dividends on the investment for the country, which after all, must be the criterion of the success of a humanitarian effort if it is to be enduring.

Colonial Medical Reports.—No. 192.—Trinidad and Tobago.

ADMINISTRATION REPORT OF THE MEDICAL INSPECTOR OF HEALTH, TRINIDAD AND TOBAGO, FOR THE YEAR 1924.

Population.

The mid-year population has been estimated by the Registrar-General as 379,965, and this figure has been used for calculating the rates.

Births.

The number of births registered was 12,791—6,479 males and 6,312 females.

Deaths.

The number of deaths registered was 7,609—4,104 males and 3,505 females. This rate is the lowest yet recorded, and shows a decline on that of last year.

Infectious Diseases.

Enteric Fever.

The outstanding occurrence of the year was the increased prevalence of enteric fever. 1,012 cases were notified, an increase of 371 on last year and of 189 on the mean for the five years 1919-1923. There were 209 deaths.

The distribution was general. Of the nineteen sanitary districts, twelve showed increases of cases amounting to 388 over the notifications of last year, while in the five which showed decreases the cases were fewer than last year by twenty-four.

It is apparent that (1) the area most heavily affected included Port-of-Spain and the more populous districts in the northern half of the island; (2) Generally the period of greatest prevalence was during the earlier dry months in the northern area, but during the wet months in the southern area of the island.

In the year under review, cases were reported generally from different parts of districts, but frequently definite grouping following on the introduction of a first or fresh case occurred as in the following instances: (1) A young man living in Port-of-Spain took ill with fever in January. He was seen once by a doctor, but continuing ill was taken by friends early in February to a village in the country. He improved slowly. Towards the end of February a young woman, an inmate of this house, developed fever, and was removed to the house of relatives in another village. About three weeks later four persons contracted fever here. These cases were notified as enteric and subsequently nine other cases occurred. This was the first appearance of enteric fever in this village. (2) A woman living at St. Joseph took ill with fever. Medical aid was not sought and the case was removed to the house of relatives in another district. About a fortnight after arrival there a brother living in the house developed fever. A doctor was then called and both cases were certified as enteric fever. Shortly after four persons in three separate houses in the immediate neighbourhood contracted enteric fever. There had been no case in that area for over a year. (3) A young woman went from one district to another to assist in nursing her sister—a notified case. On her return home she developed enteric fever and several other cases soon followed.

Source of the Outbreak.—Detailed investigations

were made, but the results obtained, except in instances similar to those given above, do not warrant a definite statement as to source.

The relation of milk to the outbreak was carefully considered. The greater part of the milk supply throughout the colony is derived from small dairies in which methods of production and distribution are unsatisfactory. Many of these dairies have no regular customers, the milk being "hawked" and sold by retail. Detailed inquiry failed to discover any evidence of the occurrence or grouping of the cases which could be regarded as incriminating the milk-supply. From the nature of the circumstances such an investigation was difficult and unlikely to give definite results, but the conclusion that milk did not contribute to any important degree to the spread of the outbreak also receives support from (*a*) the almost universal practice of boiling cows' milk; and (*b*) the extensive use of condensed milk.

The general high endemic rate, the general prevalence of malarial fever, and the disinclination of the sick in many instances to seek or to return for medical advice, are factors which contribute to the number of unrecognized cases and carriers, and so increase considerably the difficulties of investigation. In this view the method and rate of progress of the outbreak and its occurrence in the earlier dry months—when general contamination of water supplies is unlikely—are significant and point to contact, direct and indirect, as the most important means of spread.

Control. — The measures recommended and adopted generally were: (1) removal of cases to hospital; (2) attention to personal and general cleanliness (including the care of articles of food and removal of refuse); (3) supervision and control of water supplies; (4) improved latrine accommodation and regular oiling of cesspits; (5) inoculation. The measure which gave most benefit was inoculation.

As frequently happens, when cases appeared to be increasing, contacts and others readily came for inoculation, but as cases subsided interest waned. This is unfortunate—inoculation is given free of charge, causes little or no inconvenience, and does not entail absence from work—as in a civil community the benefit derived will be in direct proportion to the interest and co-operation given by the general public. Its value in limiting the spread of enteric has been evident on several occasions; the following example has been selected on account of the rapid and striking effect: Enteric fever has been generally prevalent in the Tacarigua District for several years; the mean monthly number for the last five years was eight. In December, 1923, of twenty-nine cases seven occurred in El Dorado Village, nearly all the residents of which worked on the Orange Grove Estate. In January cases continued to occur—five were notified during the first half of the month. At the suggestion and with the willing and active co-operation of the manager of the estate, the inoculation of the population (about 800) of the village was undertaken and carried through rapidly and smoothly. The fourteenth and last case was notified on January 26, and from that date no case has been notified from that area. Cases continued to occur in the Tunapuna portion of the village and inoculations were extensively done around and about each case, with the result that cases became fewer and no case has been notified from the district during the first four months of this year (1925).

Tuberculosis.

There were 524 cases of pulmonary tuberculosis and 480 deaths registered. Of the total notifications 178 were from Port-of-Spain and 218 from the other towns and large villages in the following order: Couva forty-seven, San Fernando thirty-seven, St. Joseph twenty-nine, Princes Town twenty-four, Tacarigua twenty-three, Diego Martin twenty-one, Manzanilla twenty-one Chaguanas sixteen. No case of tuberculosis other than pulmonary was notified.

Pneumonia.

349 cases were notified with 188 deaths—113 from urban and 236 from rural districts. The cases occurred generally over the colony and throughout the year.

Chicken-pox.

Fifty-one cases were notified—sixteen from urban and thirty-five from rural districts. There was no death.

Diphtheria.

Forty-one cases were notified with four deaths—twenty-seven from urban and fourteen from rural districts.

PRINCIPAL CAUSES OF DEATH.

Deaths from the ten principal causes were 253 fewer than last year, due to the decrease in deaths in the non-tuberculous group of the respiratory diseases. The other diseases showed increases which in the following cases, malaria, diarrhœa and enteritis, nephritis and Bright's disease, are slight.

Malaria stands out as the principal cause. The increase (viz., 2) over last year is small, and the figures show a definite downward trend.

Diarrhœal diseases come next in order to malaria. The increase on last year is small, but the total deaths show definite improvement on the preceding years.

When considered as a group the principal causes show definite improvement on the previous six years.

SUMMARIES OF REPORTS OF THE MEDICAL OFFICERS OF HEALTH.

Diego Martin District.

With the exception of the increase of the numbers of enteric cases chiefly from Maraval and St. James, there has been no serious epidemic of infectious disease.

An anti-enteric inoculation campaign was carried out during the year of adults and children in the district from Four Roads backwards, the same procedure will be adopted for St James in 1925.

As regards enteric fever it can be noticed that

its periodicity coincides with the change of weather, i.e., towards the end of the dry season with a rise as the wet season establishes itself. As regards its spread—from the fact that cases occurred at such distances and such length of time from each other, one can more or less exclude the fact that the spread of infection is due to anything connected with the water supply or milk.

The climatic conditions as they exist in the Maraval Valley are extremely favourable to the growth of enteric bacilli. Its spread is largely due to: (1) infection carried by flies and other insect pests; (2) direct contact; (3) human carriers.

As regards St. James its condition from a sanitary standpoint is not at all satisfactory: (1) The streets need repair and are badly kept, the drains, large and small, always contain stagnant water in the wet season with the addition in parts of decaying animal and vegetable matter, and the sanitary inspector should be commended for the manner in which he manages to keep this nuisance in check and make it more or less tolerable. (2) Owing to the large number of cowpens in this area there are of course numerous breeding grounds for flies in the manure heaps, thus providing a dangerous and rapid agent for the spread of enteric fever.

St. Joseph District.

There was a more than usually widespread epidemic of enteric, the highest number of cases taking place in January and the smallest number in September. In spite of the investigation of milk and water supply no special source of infection was discovered. The main source of infection was from Port-of-Spain. Otherwise the health of the district was generally good.

Malaria fever has not been so prevalent as in past years.

The routine habit of treating all hospital cases and out-patients with tetrachloride of carbon was adopted, and on Caroni Estate a mass treatment of the labourers carried out. This has tended to the general health improvement of the inhabitants.

The milk supply and dairy conditions were constantly supervised and a general, if slow, improvement in sanitary conditions is reported. At the end of the year there were ninety cowsheds with concrete floors.

Cesspits were constantly visited and there is an improvement both in the building of them and in the condition in which they were kept.

Antimalarial measures were carried out as far as the money available allowed. But in this one has to rely mainly on the gradual education of the people to the necessity of co-operation with the efforts of the sanitary inspector.

Tacarigua District.

Enteric fever was prevalent among people of all ages and both sexes and was distinguished for a plurality of cases among families and contact from family to family. Histories were clearly traced. In view of the fact that carriers carried the disease long after their recovery, preventive inoculation as a permanent measure against recurrence is recommended. This was performed on 5,237 occasions, particularly among contacts during 1924. No one was turned away. It is too early to pronounce positively on the efficacy of this measure, but evidence of its success is not wanting. A fully organized plan of campaign has not yet been developed. It would be well to stabilize the measure along certain definite lines.

So far as one can judge the incidence of dysentery was particularly mild. The same may be said of influenza.

Tuberculosis ranks among the major causes of death and is favoured by the overcrowding referred to.

Vastly in excess of all the preceding—not so much as a cause of death as of ill-health and incapacity of work—appears syphilis.

Yaws, too, is fairly common. The relationship of the two diseases is disturbed. As one recedes from the towns to the country-side, yaws is the more abundant and syphilis diminishes.

St. Andrew District.

The health of the population has been fair. Malarial fever was very prevalent during the months of August, September, October and November.

There was also more dysentery than the year before.

On the other hand, the number of cases of influenza and pneumonia was very much smaller than during 1923.

There were twenty-eight cases of typhoid as compared with twenty-nine cases the year before. Inoculation of contacts was performed on an extensive scale.

The water supplied by the pipes from the Quare River continues to be satisfactory.

St. David District.

There were no circumstances affecting or threatening the health of the district.

Six cases of infectious diseases were notified during the year. Of this number one was a case of enteric fever from Grande Riviere. The other five cases were individuals suffering from pulmonary tuberculosis. There are no waterworks in the district, the inhabitants of which derive their supply chiefly from rivers. In parts of the district where rivers and streams are not easily accessible, rain water stored in cisterns, tanks, and barrels is used. The villages of Grande Riviere and Matelot are plenteously supplied with good potable water derived from rivers and streams. The villagers of Sans Souci are entirely dependent during the dry season on that part of the Sans Souci River above the village and the Betty Ravine. During this season the inhabitants of Toco, especially, and of Cumana are very hard put to in obtaining water for their domestic use. In the former village a single well supplies many a home, while in the latter villages the Tompire River—some little distance away—supplies the needs of the thirsty villagers. On the whole the quality of the water in the rivers and streams is good.

Colonial Medical Reports.—No. 192.—Trinidad and Tobago *(continued).*

Chaguanas District.

There was no epidemic nor any case of disease of an unusual or grave character.

Malarial fever of the benign type was prevalent throughout the year.

A good many cases of chronic bronchitis and ankylostomiasis were also treated.

Seven cases of enteric, fifteen of pulmonary tuberculosis and one of diphtheria occurred during the year.

Couva District.

The chief diseases causing the majority of deaths were: ankylostomiasis forty-seven, bronchitis thirty-six, malaria twenty-one, nephritis fourteen, diarrhœa twelve, dysentery seven.

The number of infectious cases notified were: enteric fever forty-nine, lobar pneumonia nineteen, broncho-pneumonia nineteen, pulmonary tuberculosis fifty-eight.

Ankylostomiasis was the cause of the largest number of deaths despite the fact the Hookworm Commission were still at work in the district.

Couva is much in need of a pure water supply.

Malaria, of course, is the prevailing disease, and is of the benign tertian type.

Venereal diseases are prevalent, especially gonorrhœa and its sequelæ.

Naparima District.

Water Supply.—For a period of the year ponds furnished the water supply in nearly all the villages. This, however, is impure, and during the dry season it becomes worse and scarce.

Latrine Accommodation.—In the majority earth closets are used, and I am now pleased to say that on all estates suitable latrines have been provided for the labourers.

Scavenging.—Seven villages are now scavenged by a cart.

Gran Couva District.

Drinking water is obtained in the wet season from rain water and in the dry season chiefly from rivers, springs and shallow wells. The rivers and shallow wells are contaminated by surface washings, but there are some satisfactory springs. Swamps and drains at Flanagin Town were regularly oiled and opened, resulting in a marked reduction of mosquitoes. There is a great improvement in latrine accommodation in the large and important villages of Flanagin Town, Mamoral, Brasso and Capara. A weekly scavenging service was inaugurated in March, 1924, at Flanagin Town. As a result there has been a decided improvement in the general cleanliness of yards, including shop premises.

Guaracara District.

The Princes Town Waterworks supplying about half the district, has been in constant operation throughout the year, and the water supplied, although somewhat hard, is otherwise good and sufficient. The remainder of the district is supplied by ponds and springs, the ponds representing rather less than one quarter of the total supply, being the only one open to serious objection.

Ankylostomiasis.—In addition to the intensive treatment of frankly ankylostomiasis cases, it is the practice in the absence of contra-indications to combine ankylostomiasis treatment with the preliminary purgation of all cases of illness, and about 20 per cent. of such cases are treated a second time. This, together with a progressive improvement in latrine accommodation, is causing the position, as regards ankylostomiasis, to steadily improve.

Malarial fever was very prevalent during the second and last quarters. The chief sources of mosquitoes are (1) the small, artificially constructed rice marshes with which the district is honeycombed, and (2) the storage of rain water. While the rainfall is abundant, these are constantly overflowing and being washed out; but at the beginning and towards the end of the rainy season the showers serve to keep just enough still water in them to afford ideal breeding places for mosquitoes.

The fever is chiefly of the benign tertian type with scattered malignant cases.

Princes Town District.

Water Supply.—A pipe-borne water supply from Montserrat hills was available on the northern portion of Savana Grande, including Princes Town, throughout the year. The quantity is satisfactory, the quality of water for drinking purposes is good, but its high degree of hardness prevents its use when rain water is available. As this pipe-borne water supply is not the only water used in the area of its distribution, it is difficult to record the result of this pure water supply on this given area. It is worthy of note, however, that whilst many cases of typhoid fever and dysentery occurred in the district beyond this water supply, the area supplied by this water service had very few such cases throughout the year.

Ortoire-Moruga District.

Malaria.—The circumstances which influence the prevalence of malaria are briefly (1) swampy lands in Tableland and Moruga districts, (2) ponds and pools with leaves and twigs, &c., at their edges, grass-grown earthen drains in cultivated lands and borrow-pits in all the sub-districts. Remedial measures of drainage of swamps and regular cleaning of the ponds and pools should be undertaken.

Water.—There is a standpipe service from the Princes Town Waterworks. This supplies a small section of the district on the Naparima-Mayaro Road. Elsewhere the people get their water supply from ponds, pools and wells which are all liable to pollution.

Nariva-Mayaro District.

A greater number of malaria and ankylostomiasis cases than usual were seen, probably due to the

large increase of pauper work at the various health offices. Biche health office was added to this district in January, 1924. The source of water supply continues to be ponds, shallow wells, and, in a few cases, tanks, cisterns and barrels.

Erin-Siparia District.

The lowlying nature of the country with abundant swamps, sluggish rivers and unavoidably insufficient drainage, and the existence of large areas of uncultivated land, are probably the principal factors causing the large incidence of malaria. Inquiry was made into the manufacture of aerated waters. No sickness can be traced to impure aerated waters, but this question needs careful attention. Scavenging has been systematically carried on at Erin, Siparia and St. Mary's Village, Oropuche.

Brighton-La Brea District.

(1) *Brighton.*—The bungalow area was maintained at its usual high standard of sanitation. At Coon Town there remain ten barracks (housing 127 men, 89 women and 114 children), which it is hoped to eliminate altogether at an early date by a further addition to the model village of New Jersey. The latter, which was first occupied in September, 1922, and is equipped with every modern sanitary requirement, still continues to be an object lesson to the neighbouring population. The cottages are neatly and tidily kept, and, with a few exceptions, possess a well-cared-for flower or vegetable garden, whilst there is every evidence of cleanliness and order in the family and bachelor barracks.

(2) *La Brea.*—Much useful work of a permanent nature was performed during the year, and certain parts of the village show a presentable appearance, but Corbeaux Town and Ladysmith are, unfortunately, still with us as landmarks of what an insanitary village can be.

Cedros District.

Water Supply.—The dry weather was a very severe one for 1924. For fully ninety days there was not an inch of rain recorded at Bonas and Fullerton villages, and the majority of the people had to resort to wells, ponds and rivers for water. Fortunately there was no epidemic of intestinal diseases.

As it is a source of difficulty and expense to get enough water for the people of these villages during the dry season, some economical method of providing drinking water has to be seriously considered by the Government, and after taking everything into consideration as to the cheapest and a wholesome method of supplying water to the people, the building of at least six cisterns of about 20,000 gallons capacity each, in different parts of the villages, is recommended, the water to be collected from the roofs of houses, government and private, and with a view to prevent waste, and also to provide cost of upkeep for cleaning cisterns, &c., the people may be requested to pay a small sum —say one cent. for every bucket of water taken—as is reported done in other parts of the colony.

The inhabitants of Granville and Chatham do not appear to suffer to such an extent as they have a greater rainfall in these parts and more rivers and springs.

Scarborough District, Tobago.

During the year under review there were twenty-nine cases of enteric fever with six deaths. Of the twenty-nine cases all but two occurred in the first half of the year. It was noteworthy that the highest incidence occurred at the end of and in the first few weeks of the wet season. Last year thirty-seven cases and the year before fifty cases occurred, so that the incidence, unlike that in Trinidad, can be considered to be on the wane. With the installation of a pipe-borne water supply in this district, I expect to see very few cases in the future. The usual preventive measures were followed, importance being placed mainly on (*a*) inoculation of contacts, and (*b*) insistence on immediate removal to hospital. All the cases occurring in this district were treated in hospital.

Malarial fever was unduly prevalent, especially in the latter part of the year—July to October. Fifty-seven cases were treated in hospital with one death (a case of malignant malarial fever from the windward side).

The number treated in hospital represent about 20 per cent. of those seen in the health offices.

During the year the Ankylostomiasis Commission worked in this district completing their labours about April. Their attentions have been directed to the other two districts.

This district was not among the heavily infected ones; a bad case is rarely seen. With the more efficient tetrachloride of carbon treatment, it should be easy to deal effectively at least with all the cases presenting obvious signs of the condition. In connection with the campaign, and prior to operations being started, a large number of new latrines were installed. This, in conjunction with the educative measures accompanying same, should tend to raise the sanitary tone of the district. During the latter part of the year a preparation of pot. sod. bism: tart. was used for the treatment of yaws instead of the novarsenobillon and neosalvarsan preparations. It has on the whole proved satisfactory and is at least, so far as a short trial can be used as a criterion, equally satisfactory as the arsenicals. It has further the advantage of being very much cheaper; of causing much less pain by the intramuscular method. A point that deserves notice is that it is in my experience more satisfactory than the arsenicals in the treatment of the chronic ulcer type of cases.

Roxborough District.

There has been no epidemic outbreak of infectious disease throughout the year. Fourteen cases were notified, of which three were cases of enteric fever. Two cases suspected to be enteric fever and notified as such turned out to be [illegible]

enteric fever. Of the remaining, nine were cases of pneumonia (4) and pulmonary tuberculosis (5).

Yaws continues to be exceedingly prevalent in this district.

Much difficulty is still being experienced in getting cases to attend for treatment uninterruptedly until cured.

Water supply is from streams, rivers and wells. This is plentiful during the rainy season, but there is no adequate storage supply to use during the dry season. All streams and rivers in the neighbourhood of houses in the hilly portions of the district are open to pollution. Except the setting aside of certain portions of certain streams near their mouths for washing purposes, &c., no steps have been taken either by the local authority or the Government to prevent pollution. Action was taken by the sanitary inspector in three cases, at Delaford, Charlotteville and Parlatuvier Roads. Two defendants were fined £1 each, the other reprimanded and discharged.

During the latter months of the year the Hookworm Commission, locally superintended by Dr. Bishop, worked in this district. Cases of ankylostomiasis now presenting themselves for treatment are few and far between and there can be no doubt whatever that the work of the Commission has been productive of much benefit. Indeed, it appears that the repetition of such a campaign at stated periods must eventually lead, together with improved sanitation, to the complete eradication of this dread and debilitating disease.

Colonial Medical Reports.—No. 193.—Ceylon.

REPORT OF THE PRINCIPAL CIVIL MEDICAL OFFICER AND INSPECTOR-GENERAL OF HOSPITALS FOR THE YEAR 1924.

POPULATION: PUBLIC HEALTH.

The estimated population of Ceylon on December 31, 1924, inclusive of immigrant coolies, was 4,861,670. 10,005 of these were Europeans.

Vital Statistics.—178,866 births were registered, as compared with 181,441 births in 1923. 122,959 deaths were registered during the year, 141,894 the previous year; a decrease of 18,935 during the year under review.

The more notable causes of death were the following diseases: Infantile convulsions, 13,899; diarrhœa, 9,026; pneumonia, 8,339; rickets 4,078; intestinal parasites, 3,246; anæmia, 2,692; dysentery, 4,080; phthisis, 3,235; dropsy, 2,580; malaria, 1,388; anchylostomiasis and its sequelæ, 1,853; puerperal septicæmia, 1,322; enteric fever, 816; tetanus, 269; rabies, 37; deaths attributed to pyrexia of unknown origin, 17,697.

A large number of the deaths registered under pyrexia of unknown origin were most probably due to malaria, as this disease is prevalent in the greater part of the island.

Malaria was prevalent to some extent during the year, and showed a slight decrease as regards hospital admissions and cases treated at dispensaries and hospital out-patient departments from the large numbers of the previous year.

26,856 hospital admissions and 925,476 dispensary cases were recorded during the year.

1,388 deaths from malaria were registered in 1924, but 17,697 deaths in 1924 were registered under pyrexia of unknown origin, and many of these were probably due to malaria.

Education and Propaganda.—Public lantern lectures in English and the vernaculars have been given at Anuradhapura, Trincomalee, Mullaittivu, Mannar, and Erukkulampidi, and lantern lectures and demonstrations at colleges and schools at Kandy and most of the above towns. Additions to the series of lantern slides and posters relative to the subject have been made, and on a few occasions selected slides have been loaned for propaganda purposes. Many thousands of pamphlets and handbills on malaria and mosquitoes have been distributed to towns and villages in various parts of the island and at Anuradhapura and Trincomalee in connection with the anti-malaria campaigns.

A course of lectures and demonstrations on malaria and its control was given during July and August to the Training Class for Sanitary Inspectors held by the Sanitary Branch of the Medical Department.

With a view to encouraging medical officers and others to take up the study of the indigenous anopheline mosquitoes, a paper on the differential characters of the larvæ and adults of the species known to occur in Ceylon has been prepared by the Malariologist. Endeavour has been made to render this article as comprehensive as possible, in order that the student may be relieved of the necessity of consulting textbooks and original papers relating to the subject. This paper will be published in the *Ceylon Journal of Science* (Section D: Medical Science) at an early date, and reprints will be distributed to hospitals and the larger dispensaries.

Larvivorous Fish.—The lines on which larvivorous fish may be utilized as a measure of mosquito control have been indicated in previous reports. The practical value of these fish is more limited than is generally supposed, and it is a mistake to imagine that under natural conditions they are of equal importance in all types of mosquito breeding places, or that they can be used to supplant the more laborious and costly methods of reduction at present adopted. Normally, their beneficial action is much restricted by nature's barriers, and it is doubtful

whether, without human assistance, their presence in natural waters has any notable effect upon the prevalence of mosquitoes. Under artificial conditions—or in mosquito breeding places which are of a temporary nature only—they, however, afford an important measure of control; and it is in this connection that their exploitation in Ceylon should ultimately prove of value. Especially should this be so in those parts of the dry zone where indigenous species do not appear to be abundant, and where innumerable confined and temporary collections of water occur during the rainy season. The formation of nurseries and systematic distribution of these fish at the onset of the monsoon to such situations as rain pools, borrow pits, wells, &c., should form part of any campaign against malaria in these districts.

The nurseries of *Gambusia affinis* (*? Lebistes reticulatus*)—"Millions"—mentioned in earlier reports have been maintained, and except in one case where contamination with oil occurred, have proved very satisfactory. The fish have increased greatly in numbers, the nurseries being well stocked, even although extensive distribution to wells and pools has taken place in certain districts. In some parts of the dry zone, however, it has been found necessary to protect the nurseries with netting or cadjans owing to the prevalence of kingfishers; these birds have frequently been observed feeding on the fish, more especially during the dry season when their ordinary sources of food supply are limited.

The attempts to establish *Haplochilus lineatus* in nurseries have again proved disappointing, and it is probable that the practical value of this fish will be restricted to those regions in which it is indigenous, and where distribution to confined or temporary breeding places of mosquitoes can be made from natural reservoirs.

Malaria Control Measures.—The anti-malaria campaigns at Anuradhapura, Trincomalee, and Mahara Jail—the latter carried out under the supervision of the prison authorities have been maintained during the past year. In these cases of the first two campaigns it is too early to attempt any estimation of results at present, especially since the works involved are still incomplete. The campaign at Mahara prison, however, is naturally a much smaller undertaking than those at the towns, and sufficient time has now elapsed to enable a fairly complete report to be submitted. At Trincomalee considerable headway has been made, but it appears probable that certain major works will be necessary in the near future.

The problem of malaria reduction and control at Anuradhapura is vastly more difficult than at either of the other places, owing chiefly to the extensive cultivation of rice by artificial irrigation within the town limits, to physical conditions resulting from past archæological works, and also to the relatively low degree of sanitation pertaining at the town. Under existing conditions, paddy cultivation in the Anuradhapura District is without doubt conducive to malaria; and when it is considered that approximately six square miles of the town area are devoted to this industry, the magnitude of the problem will be readily appreciated. In fact, it would appear that unless much stricter control of irrigation water can be obtained, and the methods of cultivation (including care of the minor irrigation channels) greatly improved, a definite reduction in the prevalence of the disease will only be attained by prohibiting rice growing in towns and villages situated in this district. There can be no doubt that the apathy, conservatism, and primitive methods of the cultivators are responsible in no small degree for the association of malaria with this industry; but it is certain that if their close and intelligent co-operation could be obtained the danger arising from the fields would be diminished.

Anti-Malaria Campaign, Anuradhapura.—In view of the results obtained from investigations pursued during the preceding year (May, 1922-23) at Anuradhapura it was originally decided to limit anti-malaria measures (commenced in May, 1923) to anti-mosquito works and systematic quinine distribution during the wet season. Other methods of control, such as those directed towards protecting the individual from bites of infected anopheles or of segregating infected persons were rejected as impracticable. The attempt to reduce the numbers of human carriers by quinine administration during the wet season of 1923-24, however, failed owing to the fact that a high percentage of the inhabitants refused to accept the drug regularly.

Anti-mosquito measures were maintained through out the year on the lines indicated in the previous report, but in addition preliminary work on what may be termed a "major" measure (Halpan-ela) was undertaken. The labour force consisted of approximately 40 convicts under the control of guards, and five coolies and a kangany forming an oiling brigade; the work was placed under the immediate supervision of Entomological Assistants G. D. A. Perera and S. L. L. Casiechetty.

Unfortunately it was not possible for a senior member of the staff of this office to be stationed at Anuradhapura, and the direction and supervision of the campaign had to be performed from Colombo. In the latter respect, however, the Chairman of the Local Board has given valuable aid, and had personally inspected the work of the brigades on numerous occasions. The cost of the campaign has so far been borne almost entirely by the local authorities, who voted Rs. 1,500 for the period May-December, 1923, and Rs. 3,000 for the year 1924. Much greater assistance financially would have been necessary, but for the fortunate circumstance of prison labour being available. During January to April the execution of minor initial measures and maintenance works was continued in the central area of the town. At the end of the latter month preliminary work on the northern portion (section 4) of Halpan-ela was commenced, and was continued until October. Subsequent to October the work included clearing, filling, and drainage measures in sections 5 and 6; and pumping dry, cleaning and introducing larvivorous fish into wells in the bazaar area.

Colonial Medical Reports.—No. 193.—Ceylon (*continued*).

Oiling as a temporary measure of control of pools and swamps which could not be eliminated or permanently improved at the time was continued throughout the year over an area with radius 1½ miles from the centre of the town. This area extended considerably beyond that portion of the town where permanent measures were in progress. The work was carried out by the special brigade mentioned above; the coolies were supplied with spraying machines, and applied oil (kerosine 1 part, fuel oil 4 parts) once each week to all recognized breeding places of anopheles.

The work performed during the year may be approximately summarized as follows: Extent of jungle and low shrub cleared, 51 acres; number of pools (including pokunas) cleared and trained, 80; content of pits, swamps, &c., filled, 278,904 cubic feet; content of earth drains and irrigation channels cleared, trained, and regraded, 350,842 cubic feet; content of new drains cut, 12,968 cubic feet; culverts reopened, 26; wells cleaned and stocked with larvivorous fish, 49. Average number of situations oiled per month: Dry season (April to September), 864; wet season (October to March), 1,688.

As stated in the report for 1923, two important problems—the reconstruction of Halpan-ela and improvement of the general drainage system, and the control of mosquito breeding in wells—remained to be dealt with in the central portion of the town. Some progress in both of these has been made during the past year, and it is hoped that by the end of 1925 the work of Halpan-ela and the introduction of larvivorous fish into wells will be completed. There will yet remain, however, the questions of reorganization and improvement of the general drainage system. During the year the local authorities have constructed several cement drains in the neighbourhood of the bazaar, but such improvements are restricted to a relatively small area, and will have little or no effect on the incidence of the disease generally. It is essential that the entire drainage system be reorganized in order that surface water during the north-east monsoon and leakage or waste from irrigation channels and paddy fields may be removed as rapidly as possible. The utilization of drains as irrigation channels by cultivators should be prohibited. Following a report to the local authorities on the condition of Halpan-ela and its relation to malaria, a conference was held at Anuradhapura on February 13, 1924. Those present were the Government Agent; the Provincial Engineer, North-Central Province; the representative of the Divisional Irrigation Engineer, Northern Division; the Secretary, Local Board; and the Malariologist. A detailed inspection of the whole course of the ela was made, and it was resolved that a survey be undertaken and levels determined at an early date. This work was commenced in April and completed in September; it was performed by the Survey and Irrigation Departments respectively. The Divisional Irrigation Engineer then proposed a scheme for reconstruction of the ela and submitted estimates of the cost. There are no apparent difficulties from the engineering point of view, and it is proposed to drain the ela to the river in three tracts by subsidiary channels. With a view to reducing expenditure under this item as much as possible, it has been arranged for the greater part of the work to be performed by prison labour. The work will be commenced in the southern portion of the ela early in 1925, and will be executed under the direction of the Divisional Irrigation Engineer.

Pending the completion of the survey and determination of levels, preliminary work, consisting chiefly of canalization and clearing, was undertaken in the northern portion of the ela from April to October. The stream in this area was in an exceptionally bad state, and it was therefore considered advisable to alleviate the existing conditions as much as possible before the advent of the wet season. This work was carried out over approximately 1½ miles of the ela, the bed being recut and built to an average width of 13 feet and an average depth of 2½ feet; nearly 210,000 cubic feet of earth were removed and employed in rebuilding the banks or filling adjoining swamps and low-lying areas. Several new drains (3,650 cubic feet) were cut and connected with the ela.

An additional nursery for larvivorous fish was constructed in April, and was connected by pipes with one of the larger pokunas in order to ensure a constant supply of water. This nursery was protected by fencing and netting and stocked with "millions"—partly from the original nursery and partly from the nursery at Jaffna.

The particular objects identified with the administration of quinine at Anuradhapura and the methods adopted to ensure its systematic distribution throughout the town were given in the previous report. The work was under the control of the Provincial Surgeon, North-Central Province, and was maintained from October 17, 1923, to March 31, 1924.

Owing to the high spleen and parasite rates (see previous report) found by random sampling of the inhabitants, it was considered impracticable to restrict quinine administration solely to those in whom definite evidence of malaria infection could be obtained. Such restriction would have involved an enormous number of blood examinations, which could not have been undertaken by this office without the assistance of several trained microscopists. It was decided, therefore, to afford every inhabitant the opportunity of regular treatment during the period in question.

PARASITE RATES, TRINCOMALEE, JUNE, 1924.

Of the total films (132) in which malaria parasites were observed, *P. vivax* (benign tertian malaria) occurred in 74·3 per cent., *P. malariæ* (quartan malaria) in 18·2 per cent., and *P. falciparum* (subtertian or malignant malaria) in 7·5 per cent. The parasite of quartan malaria was more frequently observed in children (23·1 per cent.) than in adults (12·6 per cent.), while that of subtertian malaria

occurred more often in the latter (children 5·7 per cent., adults 9·5 per cent.). The average parasite rate (14·6) in children was higher than that (9·3) found in September of the previous year, when 224 films were examined.

The quantitative investigations undertaken with a view to estimating the prevalence of anopheles referred to above are not yet completed. They were restricted largely to the larval stage of the various species concerned, since it is contended that the closer limitations of the larval environment and greater uniformity in larval habits ensure stricter accuracy of measurement than can be obtained by work with adult mosquitoes. The work was continued throughout the greater part of the year, and included the careful examination each month of various types of potential breeding places situated within the town.

Observations on the breeding of anopheles in the Admiralty area and Maniaveli were performed in January and from March to October. These areas adjoin the southern limits of the town and are extensive; they include a relatively large open marshy tract and higher lands thickly covered with scrub jungle, in which are situated numerous abandoned quarry and borrow pits. The low-lying ground in the Admiralty area contains a large number of potential breeding places of anopheles, but is to some extent subjected to tidal flushing; the water is usually salt or brackish, but during the rains become sufficiently diluted in certain situations to support the larvæ of several species. Forty situations of various types were selected for examination in this area throughout the period mentioned. In January and March the anopheles found in order of larval prevalence were *A. subpictus* (Grassi), *A. funestus* var. *listoni*, *A. culicifacies*, *A. barbirostris*, and *A. hyrcanus*, but at no time were larvæ very numerous. From April onwards the number of water collections rapidly diminished, and the degree of salinity in many of those remaining increased considerably. No larvæ of anopheles were found during the period April to October.

It would appear that less danger is to be apprehended from the actual water-logged area than from the Maniaveli quarry pits, some of which are situated within a quarter mile of Admiralty House. These pits provide very favourable breeding places for anophelines, being protected by a thick belt of low jungle and capable of retaining water for long periods. Examinations made from April to August, when most of the pits contained water, showed that prolific breeding occurred in this area, and that larvæ of *A. funestus* var. *listoni*, *A. subpictus*, and *A. culicifacies* were most prevalent. Upwards of 10 of these pits have at present been located, and fresh ones are still being formed. They are situated sufficiently near the town, however, to constitute a source of danger, and their elimination will be necessary; at present no permanent measures have been introduced in this area, control being maintained by systematic oiling.

The importance of wells as breeding places of anophelines at Trincomalee was indicated in the previous report. Nearly 800 wells are present in the town, and of these approximately 80 per cent. are constructed of stone and cement and provided with parapets. They vary considerably in depth, but many (about 40 per cent.) dry out or contain little water during the last two or three months of the hot season; in the latter condition they are not used, the water supplies being obtained from such wells as remain serviceable. Comparative observations on used and disused wells were commenced in July and continued throughout the remaining months of the dry season. Forty used and thirty disused wells which had not been stocked with larvivorous fish were selected for examination.

Breeding of Anopheles in Wells, Trincomalee.

Not only were anopheles larvæ found almost twice as often in wells which were temporarily disused, but the larvæ were far more abundant in such wells. *A. funestus* var. *listoni* was the predominant species, but *A. culicifacies*, *A. subpictus*, *A. jamesi*, *A. fuliginosus*, and *A. hyrcanus* also occurred; the three last named anopheles were, however, only found in disused wells.

The control of mosquito breeding in wells at Trincomalee, as in many other towns in the island, is a problem of considerable importance and magnitude in relation to malaria reduction. The larvæ of dangerous malaria-carrying species, such as *A. funestus* var *listoni*, *A. culicifacies*, and, in the hill-country, *A. maculatus*, are commonly found in them; and in the dry zone they act as permanent larval reservoirs during the pre-monsoon period, when conditions are distinctly adverse to mosquito propagation. Until such time as pipe-borne water supplies can be introduced, it would appear that the most promising, and certainly the most economical, measure of control will be by means of the larvivorous fish, "millions." The treatment of wells by other methods, such as sealing and instituting pumps, screening, or oiling, appears to be impracticable either on grounds of expense or because such methods would lead to opposition or incorrect usage on the part of the public. There can be little doubt, however, that the number of wells present in most towns is excessive, and that many could be abolished without detriment to the inhabitants. Rigorous restrictions must be placed upon the construction of private wells in towns, and all such wells not in constant use should be condemned and closed by the owner without delay. The formation of unbuilt or "earth" wells—no matter for what purpose they are designed—should be prohibited, and those at present existing should everywhere be eliminated. The strict enforcement of such measures in conjunction with the extended use of fish would go far towards solving the problem.

The inquiry into the incidence of malaria among the coolies employed on the Admiralty Works at China Bay was instituted chiefly with a view to determining the possibilities of malaria importation from the camp during the north-east monsoon

period. The site of the works is situated approximately ten miles by road from Trincomalee in a severely malarious district. At the time of the investigation work had been in progress for some months, and over 1,000 men were employed. Of these, however, approximately 400 only lived on the site, the remainder being recruited mainly from Trincomalee and the surrounding villages. Large numbers of the latter class returned to their homes each evening, thus ensuring close connection between the camp and the town. Spleen and blood examinations of samples of the resident coolies were made in October; 56 of 362 (15·5 per cent.) coolies showed splenic enlargement, and 6 of 158 (3·7 per cent.) malaria parasites in the blood. The spleen rates ranged in the different classes of men from 0 to 33·3 per cent., but it should be noted that the examinations were made at the end of the dry season, and that the majority of those examined had only been present in the camp for a period of two or three months. At this time mosquitoes of all kinds were very scanty, and their breeding places reduced to a minimum. The results, however, indicated that the composition of the resident labour force in regard to malaria infection was of a varied nature, and that considerable numbers of susceptible coolies were present. This fact, when associated with conditions existing at the camp and its immediate vicinity, could only be regarded as favourable to the production of an epidemic at some future date, when a more or less severe reaction upon the town might be expected. Recommendations were, therefore, made to the authorities, who instituted precautionary measures within their area.

Anti-Malaria Campaign, Mahara Prison.—As stated in the report for 1922, malaria control measures were instituted at Mahara towards the end of that year, following a severe epidemic among the prisoners and staff during June to October. The measures recommended were carried out by the prison authorities, and by the Harbour Engineer's and Public Works Departments in the areas under their administrations.

The prison is situated in the Western Province a few miles north-east of Colombo; it has been in existence for several years, but originally was not built with a view to permanency. Many of the buildings are of a purely temporary character, consisting of mud and wattle walls and cadjan roofs; they are poor and ill-ventilated, and in many cases form most attractive types of shelters—for resting and feeding purposes—for mosquitoes. Since 1915 the establishment has consisted of two jails, the old jail and the portable jail, the latter having been transported from Mankulam (in the Northern Province), and re-erected in the quarry included within the prison area. The water supply is pipe-borne, being pumped from reservoirs at Ragama. Two quarries, from which metal for the harbour and roads is obtained by convict labour, are closely associated with the prison; the larger and more important is that referred to above, the smaller is situated outside the jail premises, at a distance of approximately 200 yards from the portable jail. The lands surrounding the prison are for the most part under cultivation, consisting of coconut plantations, paddy fields and native gardens. The climate is hot and moist, similar to that of Colombo, the annual average rainfall is slightly over 90 in., the wettest months being April to June and September to November, at the onset of the south-west and north-east monsoons respectively.

Although the prison is situated in a district of low malarial endemicity, it has for years past maintained an unenviable reputation in regard to the prevalence of malaria. The annual reports for recent years of the resident medical officers contain particular reference to this disease, the increased severity of which it is maintained dates from the establishment of the portable jail. Attempts to control the disease were made in 1915, 1916, 1918 and 1919, but the measures adopted (quinine prophylaxis and occasional oiling of pools), although affording a temporary measure of relief, were not such as to confer permanent improvement.

Investigations made with a view to instituting a definite campaign against malaria were commenced during the epidemic in September, 1922. At this time very numerous cases were applying daily for treatment, and hospital accommodation was possible only by the conversion of prisoners' wards. The epidemic was by no means confined to the convicts, and members of the staff and their families resident at, or in the immediate vicinity of, the jail also suffered severely.

The forms of malaria present at the time of the epidemic, and their relative prevalence as determined from films (31) in which parasites were observed, were: benign tertian (*Plasmodium vivax*) 51·5 per cent., subtertian or malignant (*P. falciparum*) 48·5 per cent. No parasites of quartan malaria were seen. Subtertian malaria was distinctly more prevalent than has been observed elsewhere, extended investigations having shown it to be responsible for an average of approximately 10 per cent. only of malarial infections.

A mosquito survey of the jail and its immediate neighbourhood showed that breeding places of several species of anopheles were present. Adult anopheles, however, were not abundant at any time during the investigation, and although careful search was made in the early mornings and evenings, very few specimens were obtained. Dissections of the latter, made with a view to definitely incriminating the active malaria-carrying species, gave negative results. Larvæ or adults of the following species were found in the course of the survey: *Anopheles barbirostris*, *A. culicifacies*, *A. fuliginosus*, *A. funestus* var. *listoni*, *A. hyrcanus*, *A. jamesi*, *A. subpictus* and *A. subpictus* var. *vagus*. Breeding places of all these anophelines were found both within the prison premises and in the surrounding neighbourhood, but those of *A. culicifacies* and *A. listoni* were much more numerous in the former area. This was particularly the case with *A. culicifacies*, the larvæ of which were found to a very limited extent outside the jail

boundaries. In this connection it is of interest to note that both *A. culicifacies* and *A. listoni* are relatively uncommon in the district generally, and that the former—which becomes much more plentiful in the drier districts further north—appears to be very restricted or local in its distribution in this region.

The remaining species of anopheles, with the exception of *A. fuliginosus*, which was found in only one situation (within the quarry), appeared to be plentiful, their larvæ being numerous in adjoining paddy fields, road drains overgrown with vegetation, coconut trenches, &c. The results of the survey appeared to indicate that anti-mosquito measures could be largely confined to the jail premises and the quarries, and that except in one area little was required elsewhere. The chief breeding places of the two important species mentioned above were (1) the ella and quarry drains; (2) wells and bathing pools; (3) small pools in the irregular surface at the foot of the working face of the quarry; and (4) newly formed trenches in the coconut plantation adjoining the southern boundary of the prison. The stream or ella flowed along the eastern boundary of the prison and passed within a few yards of the portable jail; the bed was in places composed of rock, containing numerous pot-holes, and at intervals partially blocked by masses of stone and weeds, or considerably narrowed by infringement of the banks; in many places also the sides were built of pieces of rock, the interstices between which formed excellent larval shelters. The quarry drains were badly graded, and, except during heavy rain, contained many small pools; they were in poor condition, and were insufficient to eliminate seepage water from the face of the quarry. It was, moreover, a common practice of the convicts to construct temporary dams in these drains in order to form pools in which to perform their ablutions, and to soak their baskets preparatory to repair. Wells and bathing pools were very numerous, particularly within the quarries; these pools, which were shallow and faced with pieces of rock, provided with very favourable breeding places for *culicifacies*.

The pools at the foot of the working face of the quarry were prolific breeding places of both *A. culicifacies* and *A. subpictus*. As the face of the quarry receded, the irregular surface at its base produced by blasting and other operations was filled and levelled, but such measures could not be carried out in the actual working area, and therefore numerous small pools were invariably present. Larvæ of *A. culicifacies* and *A. subpictus* were abundant in the newly cut trenches in the adjoining coconut estate, these being the only breeding places of the former species found outside the quarries; old trenches overgrown with vegetation were present in considerable numbers in the surrounding neighbourhood, but many were used for soakage purposes and were negative, while those in which the water was not polluted were only found to harbour larvæ of *A. barbirostris*, *A. hyrcanus*, *A. jamesi* and occasionally *A. subpictus*.

The results of these investigations indicated that the main factors responsible for the severe incidence of malaria at the prison and its almost complete restriction to so limited an area were:

(1) The continued presence and close association of a large body of convicts drawn from all parts of the island, and invariably including a number of infected persons[1].

(2) The presence in the immediate vicinity of numerous collections of water favourable as breeding places of two efficient insect carriers of the disease—*A. culicifacies* and *A. funestus* var. *listoni*—and the relative scarcity of these two anophelines, particularly the former, elsewhere.

(3) The presence of an abundance of food supply—the blood of persons living in the jail—for the anopheline mosquitoes close to their chief breeding places, and the relatively sparse population and scattered distribution of dwellings in the surrounding districts.

A report with recommendations for control and prevention was submitted to Government at the end of September, 1922, and was shortly followed by a detailed inspection of the prison area. The officers present at the inspection included the Principal Civil Medical Officer, the Director of Public Works, the Inspector-General of Prisons, the Sanitary Commissioner, the Deputy Harbour Engineer, and the Malariologist. As a result of this inspection a report, supporting and, in certain instances, extending the recommendations previously made by the Malariologist, was forwarded to Government.

In view of the results of the investigations, and of the difficulty of determining to what extent it would be possible to deal effectively with breeding places of anopheles on private lands in the vicinity of the jail, it was considered advisable to await the effects of anti-malaria measures in the prison area before attempting any works outside that area. The measures recommended were, therefore, largely restricted to the jail premises and the adjoining quarries; they may be summarized as follows:

(1) *Improvement of Buildings.*—Structural alterations and additions to the staff quarters or preferably the erection of entirely new quarters of a superior type sufficient to house the entire staff prevent any of the subordinate officers having recourse to existing miserable dwellings in the near vicinity.

The extension and improvement of the hospital accommodation for both the staff and the convicts, including the provision of mosquito-proof wards for acute cases, and the erection of two additional wards of fifty beds each for convalescent cases. Alternatively, in view of the expense connected with such improvements, it was recommended that the building of the proposed new prison at Ragama be commenced with the least possible delay.

[1] The Resident Medical Officer reports that of 847 prisoners admitted to the jail in 1924, 595 (70·2 per cent.) had a previous history of malaria.

Colonial Medical Reports.—No. 193.—Ceylon *(continued).*

(2) *Quinine Administration.*— Arrangements to be made by the prison authorities for the compulsory curative and preventive treatment of prisoners and members of the staff and their families, especially with a view to sterilizing existing human carriers and reducing the number of relapses and new infections. Such treatment to be applied also to all new arrivals at the prison in whom evidence or history of infection with malaria was obtained. These measures to be continued until anti-mosquito measures were completed, or until such time as it was considered advisable to modify or suspend them.

(3) *Transference of Staff.*—The transference to non-malarious stations of all officers—particularly if married—in whom symptoms of malarial cachexia or severe malarial infection were present, after they, and if necessary their families, had undergone the above treatment for a period of not less than one month.

(4) *Reduction of Labour.*—The daily task of all prisoners engaged on work in the quarries, and undergoing the above treatment, to be reduced until such treatment was completed.

(5) *Anti-Mosquito Work.*—The inauguration of suitable measures directed primarily against the species *A. culicifacies* and *A. funestus* var. *listoni*, to reduce the number of their breeding places or to render such places unfavourable for breeding purposes.

The measures proposed under heads (2) to (5) above were instituted without delay. The systematic administration of quinine was under the control of the Resident Medical Officer, and anti-mosquito works were carried out by gangs of prisoners under the direction and supervision of the Harbour Engineer's and Public Works Departments.

All superfluous bathing pools and wells were immediately closed, and those remaining stocked with larvivorous fish. These fish were also introduced into a rock-built tank—in which culicine larvæ were abundant— with a view to forming a nursery and ensuring future supplies. The general drainage system of the main quarry was much improved, and existing drains were regraded and lined with cement; the practice of damming these channels was prohibited, and all pools formed in this way eliminated. Depressions containing, or liable to contain, water at the base of the working face of the quarry were temporarily filled with sand or oiled once each week. Improvement of the bed of the stream mentioned above presented the chief obstacle in connection with anti-mosquito measures. It was originally recommended that the bed be recut throughout its course in the jail premises and for a distance of one-half mile on each side of the boundaries. This, however, was not considered feasible in its entirety, and less laborious and expensive measures were provisionally adopted. Briefly, the stream was rebuilt and regraded everywhere, except in those portions of its lower course where such work entailed cutting through solid rock: the banks were constructed of pieces of rock, and all interstices filled with cement to a height of several inches above the level of the water. A dam provided with a sluice was then erected a short distance above the rock-bound situations in order that every few days, when sufficient head of water had accumulated in the upper portion of the stream, strong flushing could be obtained. Repeated observations made subsequent to the erection of the dam indicated that this method of treating the stream was satisfactory, provided the sides and channel were kept free from weeds and debris. Indigenous larvivorous fish (*Haplochilus lineatus* and *Rasbora daniconius*) were numerous, and in the area above the dam—where prior to flushing an unbroken sheet of water existed—were able to exert their beneficial action to its fullest extent. Examinations made both above and below the dam showed that under these conditions anopheles larvæ were extremely scanty, and on several occasions none was found within approximately 200 yards of the boundaries.

In addition to the anti-mosquito measures outlined above, a permanent brigade (consisting of ten to twelve convicts, was formed for maintaining such measures in good condition. The duties of this brigade, which was under the control of the prison superintendent, included the regular clearing, flushing, and, if necessary, repair of the ella and quarry drains, the temporary filling and weekly oiling of pools near the face of the quarry, the removal of rank and low-growing vegetation, the collection and disposal of old tins, coconut husks, &c., and similar works. This party also extended their activities to the care of drains on private lands adjoining the prison.

Larvivorous fish were introduced into the coconut trenches mentioned above, but no further action was possible. These trenches are now overgrown with vegetation, and larvæ of *A. culicifacies* have not been found in them for more than one year. At an early date, however, this plantation was thoroughly cleared and numerous pits and holes obliterated. This was done mainly as a demonstration to the neighbouring landowners to indicate the lines on which co-operation was required. Propaganda work performed and breeding places of anopheles demonstrated, but although considerable interest was shown at the time, little or no response to the appeals has been made.

Cholera.—17 cases of cholera with 14 deaths were reported during the year. Of these, 1 occurred in Colombo town, 1 in the port of Colombo, 1 in the North-Western Province, 4 in the Central Province, 1 in Sabaragamuwa, and 9 in Uva, where there was an outbreak in 1919-20. There were no cases during 1921, 1922 and 1923.

Small-pox.—There were 45 cases with 9 deaths, as against 240 cases with 35 deaths the previous year. Of the cases reported during the year, 4 cases were landed in Colombo from steamers, 4 cases occurred in Colombo town, 8 cases were admitted to the Infectious Diseases Hospital, Colombo, from the neighbouring villages, 1 occurred in the North-Western Province, 1 in Sabaragamuwa, 1 in the

Central Province, and 26 cases with 5 deaths in the Northern Province, where there was an epidemic in the Jaffna Peninsula in the last quarter of the year.

Vaccinations.—The total number of primary vaccinations performed during the year was 128,591, of these 123,009 were successful and 2,775 were failures. In 8,465 cases the results were not determined. Vaccination is carried on throughout the year by trained male and female vaccinators, the former vaccinate in the towns and villages and estates periodically according to annual programmes of vaccination, and the latter itinerate in the towns and villages to vaccinate Muslim women and children.

Enteric Fever.—The total number of cases treated in Government hospitals during the year was 1,600 with a death-rate of 25·5 per cent., as against 921 cases with a death-rate of 29·31 per cent. in 1923. The increase in hospital admissions is partly due to the activities of the Sanitary Branch in discovering cases and recommending hospital admission. The number of hospital admissions again does not indicate the actual prevalence of the disease, for some cases reported as deaths from pyrexia are due to enteric fever, although the bulk are probably due to malaria. The Registrar-General's returns show that 816 deaths from enteric fever and 17,697 deaths from pyrexia of unknown origin were registered during the year, and undoubtedly some of the latter should have been included in the former. The corresponding figures in his returns for the previous year were 597 and 23,328 respectively. Patients are usually taken to the hospitals for admission in late stages of the disease, and the mortality rate of these cases is therefore high.

Diphtheria.—Nineteen cases with seven deaths were recorded during the year, as against 15 cases with 6 deaths during the previous year. Of the former, 8 cases with 2 deaths and 1 case with 1 death were reported from the Infectious Diseases Hospital, Colombo, and the General Hospital, Colombo, respectively. Three cases with 1 death from the Western Province, 6 cases with 2 deaths from the Central Province, and 1 case with 1 death from the Northern Province.

Influenza.—A mild form of influenza prevailed in all the provinces at different periods of the year; 3,888 cases were treated in Government hospitals with 115 deaths, a mortality rate of only 2·9 per cent. The corresponding figures for the previous year were 4,443, 162, and 3·64 per cent. respectively.

30,719 cases were treated at dispensaries during the year, against 23,372 cases in 1923.

Of the total number of cases treated during the year, 5,112 out-patients and 1,233 in-patients were treated in the Western Province, 15,544 and 1,208, respectively, in the Central Province.

Dysentery.—Cases of dysentery were reported from all the provinces during the year. The number treated in Government hospitals was 6,165, with 1,217 deaths, as against 5,884 and 993 respectively the previous year. Of the in-patients treated during the year, 1,123 cases with 112 deaths were reported from the Western Province, 1,022 cases with 237 deaths from the Province of Sabaragamuwa, and 1,335 cases with 423 deaths from the Central Province.

Drinking water obtained from shallow, unprotected wells is the most common source of infection, and usually heavy rains with consequent flooding causes pollution of the villagers' water supply. 4,080 deaths from dysentery were registered by the Registrar-General's Department during 1924, as against 3,326 in 1923.

Cancer and Sarcoma.—The number of patients admitted to the various hospitals during the year with malignant growths was 434 with 57 deaths, as compared with 443 cases with 59 deaths in 1923. The total number of deaths from "cancer of malignant diseases" reported by the Registrar-General was 473, as against 433 registered in 1923. 28 cases of cancer were admitted to the Lady Havelock Hospital for Women, Colombo, during the year under review: of the cervix uteri 23, breast 2, bowel 2 and glands of neck 1 (secondary).

The admissions during the previous year were cancer of the cervix uteri 17, of the uterus 4, ovary 1, breast 2, liver 1, bowel 1, vulva 2, vagina 1, rectum 1, and anus 1. The average age was 38·96 in 1924, 41·16 in 1923.

Ankylostomiasis.—153,488 cases were treated at dispensaries during the year.

These figures refer to cases of ankylostomiasis as the primary disease; but owing to the almost universal infection of all hospital and dispensary patients, mass treatment for this disease was carried out during the year at dispensaries and hospitals, and a large number of persons received necessary treatment.

Tubercular Diseases of the Lungs.—The number of hospital cases treated during the year was 3,657 with 860 deaths, as against 4,099 cases with 990 deaths in 1923.

Leprosy.—Two asylums are maintained in the island for the segregation of lepers under the Lepers Ordinance, No. 4 of 1901—at Hendala in the Western Province and the Island of Mantivu, in the Eastern Province. They are nursed by religious sisters with the help of male and female attendants at both asylums.

There were 114 lepers at Mantivu island on December 31, 1923. 48 were admitted during the year, 12 died, 31 were discharged or absconded, and 119 remained on December 31, 1924. Of the admissions, 14 were new cases, 31 readmissions and 3 absconders from the Hendala Asylum. The daily average in the asylum during the year was 112·95 per cent., and the percentage of deaths 7·41.

The report of the Medical Superintendent in charge of the asylum at Hendala gives the following figures for the year under review: Remained on December 31, 1923, 516; admitted during 1924, 135; discharged, 77; died, 51; remained on December 31, 1924, 523.

Of the 135 admissions, 110 were new cases; 17 of these, 9 were of the tubercular type, 29 of the

anæsthetic type, and 72 of the mixed type. The new admissions were from the following provinces: Western 62, Central 12, Southern 14, Northern 6, North-Western 3, Sabaragamuwa 6, and Uva 7.

The Medical Superintendent reports 146 lepers were treated during the year with E.C.C.O., 3 of these were discharged cured in October last, many of the younger subjects under treatment who have been regular have shown marked improvement, and if this regularity is maintained still better results can be expected in the near future.

There has been steady progress in the early cases under this treatment, and there are a number of patients now in the asylum whose discharge as cured will soon have to be considered. The majority are, however, in the last stage of the disease and of the advanced crippled nerve type, and these can only hope for some relief, some improvement in their general health from this treatment.

Parangi (Frambæsia, or Yaws).—The number of hospital admissions was 6,149 with 18 deaths, as against 9,748 admissions with 32 deaths in 1923. The decrease in the number of admissions to hospitals during the year was due to intensive campaigns by seven itinerating medical officers in the Central, Southern, Eastern, North-Western, North-Central, Uva and Sabaragamuwa Provinces, and the treatment of a large number of out-patients brought in by headmen and voluntarily seeking treatment at dispensaries and the out-patient departments of hospitals. The seven itinerating medical officers treated a total number of 17,852 cases, and a large number of these patients attended a second and a third time, and 33,052 injections were given during the campaign in 1924, as against 16,815 cases and 30,139 injections in 1923.

Plague.—There were 153 cases (Colombo town 148, Kalutara 1, Talaimannar 1, Peliyagoda, near Colombo, 1, and Talawakele bazaar 2) during the year with 145 deaths, as against 232 cases with 211 deaths in 1923, 160 cases with 150 deaths in 1922, 187 cases with 171 deaths in 1921, and 369 cases with 316 deaths in 1920. Of the 153 cases reported, 59 males and 12 females were admitted to the Infectious Diseases Hospital, Colombo, 62 were bubonic, 7 septicæmic, and 2 pneumonic. The septicæmic and the pneumonic cases proved fatal, and of the total number of cases treated during the year 19·2 per cent. recovered, as against 15·68 per cent. recovered the previous year.

Port Health Precautions.—During the year 2,584 British and foreign steamers and 297 native sailing vessels called at the Port of Colombo and were inspected, as against 2,363 steamers and 285 sailing craft in 1923.

Six steamers arrived infected and were placed in strict quarantine; of these, 3 arrived with small-pox, 1 with cholera, 1 with cerebrospinal fever and 1 with typhus. All the cases were landed and sent to the Infectious Diseases Hospital. 7 cases of chicken-pox were landed during the year.

Of the samples of water taken from the water boats and sent for analysis only two were condemned, and necessary action immediately taken to have the boats cleaned and cement-washed.

The number vaccinated during the year was 5,963, mostly arrivals foom India *viâ* Tuticorin.

Disinfection of 152,934 persons and their clothing was carried out at the port disinfecting station.

At the port venereal clinic for seamen 61 cases of syphilis were treated by intravenous injections in 1924.

Medical Inspection of Schools.—The routine inspections of all the more important schools were carried out on the same lines as in previous years, individual pupils being examined in detail for any chronic disabling conditions. The number of schools examined was 72 boys' and 81 boys' schools, the total number of children being 3,570 boys and 5,209 girls. As in previous years, the most common disabilities in the children of urban schools were dental disease and defective vision, and in rural schools infection by hookworm and malaria. In the former case the degree of visual defect was rarely such as to interfere with the progress of the child in school, although in a few instances it exceeded 6/12 D. Less numerous and, yet perhaps, more serious among eye diseases met with, were cases of chronic follicular catarrh, due largely to imperfect treatment of acute ophthalmia. These cases undoubtedly constitute the sources from which, under favourable conditions, serious epidemics of acute disease occur. Dental disease is becoming more numerous among school children, especially of urban areas; a large number of the cases have advanced to such a stage that no conservative treatment can be adopted; younger children go about with retained milk teeth on account of the difficulty of obtaining relief; many cases with early caries are frequently absent from school on account of attacks of pain. Dental treatment under existing conditions in Colombo and the outstations is beyond the means of the average parent; an extraction or a single filling costs as much as Rs. 5, and medical inspection of schools will never realize its full results until better facilities for treatment are provided by the State. The urgency exists only in the larger towns, and as soon as a central institution in Colombo is opened, it would be possible to arrange for occasional visits of a travelling clinic to smaller towns.

The problem of malaria among school children is part of the problem as it affects the whole island. Side by side with the development of the sanitary part of the campaign, strong educational efforts must be made to secure the right response from the public. It is hardly likely that the anopheles mosquito will ever be exterminated from the island, but it has been declared that "given sufficient quinine and a public ready to co-operate with the health authority, malaria may be got rid of in any part of the world." The suggestion here, of course, is that all human malaria carriers can be sterilized, rendering the mosquito harmless in its relation to the disease. This implies that all persons infected with malaria should be treated with quinine until the sufferer's blood is declared

parasite-free. A radical measure of this kind is bound to meet with considerable opposition unless the ground is prepared in the schools. It has been possible to control the epidemic incidence of small-pox by compulsory vaccination of all children before admission to school; in a similar manner some attempt at thorough treatment of all malaria carriers will have to be carried out in some of the more important Government schools situated in malarial districts.

Regarding hookworm, with the facilities now available, both for examination and treatment, the severity of infection can be effectively controlled. Recently a sum of money was voted by Government for the erection of school latrines, and a plan providing a compartment for a bucket and an ablution chamber has been approved.

The propaganda of the hookworm campaign and the operations of the directors have popularized the specific treatment in the schools, and it only remains now to ensure that the schools are regularly visited and the measures to prevent reinfection are perfected.

An unusual number of cases of itch was noticed in the Matara schools, and the infection has probably been carried to these schools from the neighbouring dry districts of Tangalla and Hambantota; lack of sufficient water for bathing purposes is undoubtedly one of the predisposing causes of the spread of this disease, but that factor hardly operates in Matara, where no doubt the ignorance of its parasitic and contagious nature favours its spread.

During the year a number of vernacular schools in the Western and Southern Provinces were visited in order to ascertain their sanitary condition and the kind of instruction that is given in hygiene. The buildings are mostly of the single-hall type with a low wall, some of them are paved and cemented; the old-fashioned long benches are everywhere in use, and in some the accommodation was seriously taxed; the sanitary conveniences consisted of a cesspit only in some of the schools.

Two periods a week are set apart for a class lesson on hygiene, and some elementary books are prescribed for study, but these lessons in several schools were lacking in detail and practical value, and in some instances the teacher was obviously ill-equipped for the task himself. Instruction in hygiene for children in these schools should be directed towards the cultivation of hygienic habits and demonstrations in certain sanitary methods. It is the development of the "Sanitary Conscience" so neglected in these children and so vital to the sanitary progress of the country that should be promoted. The more backward the locality in which a school is situated the greater the care that should be paid to the sanitary details of the school and its equipment. The site, the locality, and the building, with its drainage, water supply and sanitary conveniences should be such as to afford a permanent object-lesson in essentials; the cleanliness, repair, and equipment should always be above criticism. Such a standard will, however, not be attained until specific conditions are laid down as to what is the minimum required before registration. The Code has laid down certain conditions relating to school buildings and their sanitary condition, which have to be complied with before registration; but they should be further amplified by insisting on provision being made for play-ground accommodation, water supply and latrines, and these should be of a type that has the approval of the education department.

The work of the treatment clinics has continued during the year, the total number of cases at the Eye Hospital being 268 and at the Anti-Tuberculosis Institute 215. These children paid a total number of 724 and 713 visits, respectively, during the year. Of the 268 children treated at the Eye Hospital 140 were eye cases, 81 throat cases, 39 ear cases, and 8 nose cases.

The school nurse reports a distinct improvement in the health of the school children and that parents are less averse to treatment by minor operative measures. In some cases they will travel many miles to see the lady doctor at the school clinic.

In all some 8,779 children were medically examined and defects or ailments found in 1,963 of them, as against 8,588 and 2,158, respectively, the previous year.

Scientific Section.

Government Bacteriological and Pasteur Institutes.—Report of the Director, Dr. Lucius Nicholls, for the year 1924:—

A.—Bacteriological Institute.

Routine Work.—The number of specimens examined during the year was 8,228. The fees which were received for the examination of specimens, not sent from Government institutions, amounted to Rs. 5,972, and were credited to revenue.

The Bacteriological Examination of Water.—Samples of 83 different sources were examined during the year.

On several occasions during past years a sample has been received at this laboratory and has been of excellent quality, and at a later date another sample has been received from the same source and has been condemned as unfit for human consumption.

Because such results as these have been considered extraordinary by the senders of samples, it appears that misapprehensions and hazy ideas exist as to the meaning and value of bacteriological and chemical examinations of water for drinking purposes.

It should be understood that the result of the examination of one or more samples from any water supply is only of value when it is considered in conjunction with the thorough inspection of the source of the supply, such as the catchment area, by a sanitary expert.

Colonial Medical Reports.—No. 193.—Ceylon (*continued*).

The contamination of the water supplies is usually intermittent, and even when half a dozen or more samples from a supply have been found to be chemically or bacteriologically pure, very little reliance can be placed upon this unless the catchment area of the supply is properly conserved.

A water may be bacteriologically pure for 99 days, and on the 100th day excessive rains or some other adventitious occurrence may cause contamination of the water supply. The following is a good example of this:—

The water supply of Diyatalawa was examined on two occasions and found to be bacteriologically pure. After heavy rains the same supply was found to be teeming with "fæcal" bacteria. It was discovered that during these rains the drainage from the coolie lines and a tea estate was washed into the supply. In other words, the catchment area was not properly conserved, and yet, during dry weather, the water percolated sufficiently through the earth for natural filtration to purify it. In this case the military authorities had relied on the early chemical and bacteriological examinations and were misled as to the purity of the water.

It is desirable, especially in the case of expensive town installations of water supplies, that the bacteriologist should visit the catchment areas with the engineer and collect the samples himself. It is important that the bacteriologist who examines the samples of water should have first-hand knowledge of the sources of them.

Research Work.—During the year the *Ceylon Journal of Science* came into existence, and the medical section of this paper is edited by the director of this institute. Any research work of importance which is carried out at this institute will be published in this journal.

Much work was done during 1924 on the morphology of bacteria when they are growing under various circumstances such as when growing on 3 per cent. salt agar, or on salt-free agar. It was found that many organisms could be quickly recognized by this method of comparing their morphological appearances on two or more media. Papers on this subject are now in the press.

Work was done on the development of "local" immunity to *B. pestis* and *B. anthracis*. Various vaccines suitable for administration by the mouth or application to the skin were prepared from these organisms, and attempts were made to immunize rabbits and guinea-pigs by feeding the vaccines to them or rubbing the vaccines into the skin. But as far as these organisms are concerned, immunity sufficient to protect the animals from plague or anthrax did not develop in a single rabbit or guinea-pig. The details of this work are being published in the number of the *Ceylon Journal of Science* which is in the press.

Work was done on *B. pyocyaneus*. This organism appears to be pathogenic under three circumstances:—

(*a*) As a secondary invader after such diseases are typhoid. The best example of this was a case of pericarditis following typhoid in which the organism was present in pure culture.

(*b*) As a secondary invader after such diseases sent to this laboratory a number of specimens which have been obtained from a duodenal tube. The specimens have contained *B. pyocyaneus*. And in two cases when the symptoms have abated and the patients have returned to normal health *B. pyocyaneus* ceased to be present in the duodenal fluid.

(*c*) *B. pyocyaneus* has been isolated on a number of occasions from light-coloured choleraic-like contents of the ileum which have been obtained from patients who have died suddenly with symptoms resembling cholera. We have never isolated *B. pyocyaneus* from cases of cholera when the *V. choleræ* has been present.

It appears probable that in Ceylon there exists an acute intestinal disease closely resembling cholera, but which is due to a highly virulent strain of *B. pyocyaneus*.

Another organism which requires further investigation is one which closely resembles *B. diphtheriæ* and which has been isolated from chronic ulcers of the leg and from a peculiar type of throat ulceration.

B.—Pasteur Institute.

During 1924, 398 patients were treated for dog bites. Besides these a large number of persons sought advice at the institute.

The number of patients who have been admitted for treatment at the institute since its opening up to the end of 1923 is 1,777, and 21 of these have died of hydrophobia. This is 1·18 per cent. of failures.

Summary of Results of Research Work done in the Municipal Bacteriological Laboratory during 1924 by Dr. L. Fabian Hirst, Municipal Bacteriologist, Colombo.

(1) The flea survey of Colombo was completed. The total number of fleas examined in the course of the survey was 10,994 taken from 3,331 rats of all species.

The town was divided into fifteen districts, including the Customs premises and Government granaries.

The co-efficient of correlation between percentage *Xenopsylla cheopis* to total rat fleas and human plague incidence per 10,000 of population in the fourteen inhabited districts was ·95 probable error ·02. The various factors which might produce a spurious correlation between cheopis prevalence and plague incidence were separately examined. The results were negative.

Similarly a most striking agreement was disclosed between the actual distribution of cheopis-infested premises and the situation of premises where plague rats were found.

The results of the flea survey show that the percentage of *Xenopsylla cheopis* found on rats in the Government granaries and Customs premises is much higher than elsewhere. An equally high proportion of *X. cheopis* is found on rats caught in the municipal grain boutiques.

The *X. cheopis* found during the flea survey on the rats of Fourth Cross Street, where much grain other than rice is stored, were 45·9 per cent. of 274 fleas. During the epizootic of rat plague, which took place in that street during November, 1923, the proportion of *X. cheopis* rose to 80 per cent.

The rats caught in Bankshall Street, which also contains much imported grain, during the flea survey harboured 44·8 per cent. *X. cheopis* out of a total of 58 fleas.

The proportion of *X. cheopis* in the outlying markets at Dean's Road and Nagalagam Street, where a strictly limited amount of grain is permitted to be stored, was 7 to 8 per cent. In the outlying districts of the town the percentage of *X. cheopis* varied from 2 to nil.

Comparative Experiments on the Transmission of Plague from Rat to Rat by means of X. astia *and* X. cheopis.

1. Attempts to transmit plague between rodents have been carried out with 596 *X. astia* in the course of 13 experiments during four plague seasons at room temperature in this laboratory. The results were entirely negative.

(2) Under similar conditions 132 *X. cheopis* transmitted plague to twelve rodents in the course of six separate experiments.

(3) Plague has been transmitted from rat to rat by means of *X. astia* in one experiment carried out at an artificially reduced temperature in a transmission chamber surrounded by a mixture of ice and sawdust. One infective *astia* was found to be typically "blocked" and exhibited the phenomenon of œsophagal regurgitation described by Martin and Bacot. Two other experiments on the same lines gave negative results. In other words, *X. astia* may carry plague of rats, under climatic conditions favourable to plague transmission.

(4) Contrary to my expectations, plague was continuously transmitted to a series of rats in succession by the same batch of infected *X. cheopis* at room temperature during March, 1924, under climatic conditions particularly favourable to plague transmission.

(5) It is comparatively easy to obtain heavy growth of plague in the stomach of *X. astia* fed upon infected plague rats. There is evidence, however, that blocked *astia* may have relatively low vitality and bite rats but feebly at tropical temperatures.

(6) No evidence has yet been obtained of any marked difference in the virulence of *B. pestis* after growth in the stomach of *X. astia* and *X. cheopis*.

Spinal Analgesia by Dr. Lucian de Zilwa, Physician, General Hospital, Colombo.

In November, 1922, I did my first operation with spinal analgesia caused by injecting a bulb of stovaine into the spinal canal in the lumbar region. Since then all major operations have, whenever possible, been done under stovaine. In 1922, 12 operations were done under stovaine; in 1923, 67; and in 1924, 145. The smallness of the earlier figures is explained by the difficulty in obtaining stovaine in sufficient quantity. The almost total prevention of shock, and the completeness of abdominal relaxation with a localized anæmia, make stovaine an ideal anæsthetic for major operations. It is not given for minor operations like curettage of the uterus. Only in one instance was there a misadventure, where the patient lay down almost immediately after the injection had been given Since then particular care has been taken to keep the patient either seated or with head and neck elevated for ten minutes after the injection.

In 14 of the above 224 cases of spinal analgesia it was found necessary to administer a little chloroform, either because the patient was nervous, in spite of being analgesic, or because at the end of a long operation there were indications of a recovery of sensibility. In four cases no analgesia was produced, although two bulbs of stovaine had been injected into the spinal canal. One of these women admitted drinking about two bottles of arrack daily.

In none of the cases were there any unpleasant effects observed. Even the severe headache, on which much stress is laid in the literature, was only noted in four of the patients.

A Brief Résumé of a few interesting Cases by Dr. A. M. de Silva, Surgeon, General Hospital, Colombo.

Intestinal Obstruction due to a Meckel's Diverticulum which was gangrenous. In this case the Meckel's diverticulum had formed a noose round a coil of small intestines and tightly constricted it producing acute obstruction—the end of the diverticulum was firmly attached to the mesentery. The whole of the diverticulum, together with a portion of intestine to which it was attached, was gangrenous. The gangrenous portion was resected and intestinal anastomosis done. The patient made an uninterrupted recovery.

Intestinal Obstruction due to the Vermiform Appendix.—A somewhat similar case, only in this patient the appendix formed the band and was not gangrenous. It was acutely inflamed and firmly attached to the mesentery of the ileum. A loop of small gut was tightly constricted by it and on relieving the obstruction small patches of gangrene were found in the constricted area which were invaginated by purse-string sutures. The patient made an uneventful recovery.

Goitre.—10 operations were performed for this during the year. 8 of these were for adenomata and 2 for exophthalmic goitre. 5 of them were males and 5 females. Goitres of all varieties seem to be just as common in males as females in Ceylon. *Parenchymatous goitres* were frequently met with both in boys and girls in association with enlarged tonsils and adenoids, in these patients

when the tonsils and adenoids were removed the goitre markedly diminished in size and in no case was operative treatment required for the goitre.

Lingual Goitre.—Lingual goitres are rare. The tumour was removed from an adult male, aged 28, by an incision in the middle line of the neck extending from the symphysis to the hyoid. The tumour was just in front of the epiglottis, immediately under the mucous membrane, projecting into the pharynx and obstructing the laryngeal orifice. It was of the size of a mandarine orange. It was very vascular—a solid adenoma. Preliminary laryngotomy and tracheotomy were done as there was no palpable thyroid in the normal site, a small part of the tumour was left behind to prevent the superventure of myxœdema. The patient, although complaining of dyspnœa for a few days after the operation, made an uneventful recovery and left hospital greatly relieved.

Sacro-coccygeal Tumour.—A very large sacro-coccygeal tumour was successfully removed from an adult male—it was present from birth and was of the nature of teratoma. There was no communication with the spinal canal.

Meningocele.—A large meningocele was removed from an infant eight days old. The tumour was much larger than the infant's skull, the skin over it was thin, atrophic, and ulcerated in places. It was attached to the skull at the external occipital protuberance and communicated with the fourth ventricle. After operation the infant seemed to be getting on well, but died on the eighth day with signs of meningitis.

Granuloma of Nose causing complete Occlusion of both Nasal Cavities.—Two cases were operated on during the year, one an adult male and the other a female. Both nostrils were completely occluded by hard, firm granulation tissue of many years' duration. This tissue projected outside the nasal projections on to the face, disfiguring the patient, filled up both nasal cavities completely and also the nasopharynx; nasal breathing was absolutely impossible, the mouth was kept constantly open. Although the tissue removed was carefully examined microscopically and bacteriologically the cause of this rare condition could not be ascertained. Wassermann reaction was negative, but, in spite of this, injections of salvarsan were administered without any appreciable improvement in their conditions. The operations consisted in burrowing two tracts through the dense granulomatous masses and introducing drainage tubes, thus restoring nasal breathing. On removal of the tube the tracts tend to close, so that they were kept in and the patients discharged with the tubes *in situ*.

Splenectomy was performed three times during the year for chronic malaria—the largest spleen removed weighing 8½ lb.

Internal Ear.—Two operations were successfully performed on the labyrinth for suppuration extending to this region. After the usual radical mastoid the lateral sinus was exposed and the bone in the angle between the external semicircular canal and facial canal was chiselled into until the external semicircular canal, vestibule posterior semicircular canal and cochlea opened up. In both cases the discharge ceased after the operation.

Cancer.—The number of cases of this complaint admitted to the wards seems increasing every year, and unfortunately the majority of cases are in an inoperable stage. In some of these inoperable cases Bell's treatment (raw vegetable juices and injections of sodium cacodylate) was tried, certainly with beneficial results, though in no case had a definite cure resulted.

Injury to the Thoracic Duct in the Thorax.—This was a result of a stab wound on the left side at the level of the eighth dorsal vertebra. The patient—a lady—three months pregnant was assaulted at Badulla, where she was treated for the first few days. When admitted to the General Hospital the external wound was completely healed, but there were signs of free fluid in the pleural (left) and peritoneal cavities, causing severe dyspnœa. On aspirating these cavities large quantities of chylous fluid were removed. But the fluid, both in pleural and peritoneal cavities, quickly reappeared (within a day or two) so that repeated tappings were necessary. The pleural cavity was aspirated more than a dozen times and the abdominal cavity was also tapped about an equal number of times. After each tapping she was greatly relieved, but the fluid speedily recurred and she also aborted whilst in hospital. As tappings were required so frequently I was obliged to make a permanent opening in the thorax by resecting a portion of the rib. Although the patient was greatly relieved by this operation—the fluid ceasing to accumulate in both pleural and peritoneal cavities—she had a sinus discharging chyle continuously and was wasting rapidly. In spite of regulation of diet, &c., she continued to lose flesh and eventually died in a comatose condition several months after the original assault.

Reductio en Masse (Strangulated Hernia).—One case of *reductio en masse* was operated on during the year. The remarkable feature about this case was that the patient himself produced the *reductio en masse*. The hernia, which was previously reducible, came down and got strangulated and he was seized with violent pain and vomiting. In desperation he squeezed the whole forcibly inside the abdominal cavity—only to find that although the external swelling had completely vanished there was absolutely no relief to his symptoms—the pain was even more severe than before, and the vomiting continued. At the operation it was found that the *reductio en masse* was of the recto-peritoneal type (the sac with its contents lying between the iliac fossa and peritoneum) and the intestine was gangrenous in places. After operation patient made an uneventful recovery.

Some important factors in the causation of diabetes mellitus in Ceylon (based on a brief survey of 200 selected cases), by Dr. Lionel de Silva, physician, General Hospital, Colombo.

Funck has rightly stated that the diagnosis of

diabetes mellitus means no more than the diagnosis of fever. The chief manifestations of this disease have been recognized since the days of Celsus, and it is said that Aræteus, in A.D. 150, was the first to call this syndrome complex ætiology "diabetes mellitus." Attempts have been made from time to time to regard diabetes as a definite disease, but the researches on the biochemistry of the blood and urine during the last decade have proved the correctness of Solis-Cohen's dictum: "I do not know of any definite disease called diabetes mellitus." Hindu medical literature of the sixth century refers to this disease as "madhumeha" or honey urine, and describes it so vividly that Chander Bose's translation seems worthy of repetition. Madhumeha is a disease which the rich principally suffer from, and is brought on by their over-indulgence in rich flour and sugar. The patient feels weak and emaciated and complains of frequent micturition, thirst, and prostration, ants flock round his urine, carbuncles and phthisis are its frequent complications. This classical description adequately describes the state of the diabetic in Ceylon to-day. Careful observation and improved technique have enabled us to investigate further as to whether it is the liver, stomach, kidney, pancreas, or the nervous system which refuses first to respond to the constant strain of over-indulgence in food, alcohol, &c. The somewhat premature enthusiasm of the lay press over the valuable discovery of insulin has unfortunately created an atmosphere of optimism among sufferers, who seem to ignore the fact that several causes, operating individually or collectively, may give rise to these common symptoms which go under the somewhat unfortunate term "diabetes."

An ætiological survey of 200 cases based on clinical and biochemical observations during the last four years showed primary pancreatic involvement in only four cases.

Age when disease was first recognized:—90 out of 200 were just under 40 years, 76 out of 200 were between 40 and 50 years, 23 out of 200 were between 50 and 60 years, 11 out of 200 were over 60 years. The average age incidence of the cases under 40 years was 38 years.

It is worthy of note that the first appearance of this disease in the majority of cases in this series is much earlier than almost all other countries, including India. In European countries, especially in Southern Europe, the average age incidence has been 50 years. In Dr. Bose's series of 325 cases the majority of patients were over 40. This higher age incidence in India may be due to the fact that the individual Ceylonese is relatively more prosperous than his brother in India.

The stages in the life history of the average diabetic in Ceylon may be summed up as follows:—(*a*) Material prosperity; (*b*) over-feeding by parents, excessive indulgence in rich food and sweets; (*c*) sedentary occupation; (*d*) suralimentation leading to hepatic congestion; (*e*) occasional glycosurias due to hepatic insufficiency and in some cases excessive functional activity of the liver; (*f*) constipation and often hæmorrhoids become well-marked features in the case; (*g*) persistent glycosuria with hepatic lesions. This is the stage at which the physician is first consulted; (*h*) case becomes diabetic without denutrition, suralimentation still continued. Liver slightly enlarged, high blood-pressure and renal sclerosis. Patient eventually dies of uræmia. Average expectation of life seems to be about 10 to 15 years from onset of symptoms; (*i*) patient may become a diabetic with denutrition. Hepato-pancreatic cirrhoses with serous diabetes develops, about 5 per cent. of cases in this series.

Splenectomy, Intestinal Obstruction due to Worms, Extra Uterine Pregnancy and Perforated Typhoid Ulcer with Peritonitis, by Dr. Catherine E. Anderson, Medical Officer in Charge, Lady Havelock Hospital for Women, and Lady Ridgeway Hospital for Children, Colombo.

Case 1.—Joseph, aged 8, a resident of Ambepussa, was admitted into the Lady Ridgeway Hospital on June 9, 1924, with enlargement of abdomen and a history of intermittent fever for two years. On examination the spleen was found to be filling up the whole of the left side of the abdomen and extending across the middle line one inch to the right of the umbilicus and below down to the symphysis pubis. Blood filter showed malaria parasites. Patient given a course of iron and arsenic and quinine treatment. Splenectomy was done on July 4, 1924. Spleen weighing 1¾ lb. was removed through a vertical incision through the left rectus. He made an uninterrupted recovery and was discharged fit on August 21, 1924.

Case 2.—Caroline, aged 5 (Sinhalese), was admitted into the Lady Ridgeway Hospital on November 17, 1924, with a history of attacks of abdominal pain and vomiting and fever for 5 days, also the passage of only blood and mucus *per rectum*. The mother said she noticed a "lump" appearing in the abdomen from time to time. On admission temperature was 100° F., pulse 140; a tumour could be felt extending from under the right costal margin across the abdomen above the umbilicus to the left hypochondriac region. Several enemas were given and blood and mucus only were passed *per rectum*. Diagnosis of obstruction high up in the small intestine was made due to intussusception or possibly *Ascaris lumbricoides*. Laparotomy was done on the evening of admission through a vertical incision through the right rectus. About 18 inches of the jejunum was found to be packed by a solid mass of round worms. It was found impossible to "milk" them down the bowel, so enterotomy was done. Through this the worms, numbering about 800, were removed in masses by means of forceps—the worms being "worked" towards the aperture in the bowel until the whole mass was evacuated. A double row of silk suture closed the bowel and the abdomen was sutured up in the usual way. Saline and glucose *per rectum* were given for the next 24 hours. On November 19, 1924 (i.e., two days after the operation), ½ gr. of santonine, preceded and followed by ol. ricini, was given, but no worms were passed.

Colonial Medical Reports.—No. 193.—Ceylon (*continued*).

On November 20, 1924, the child passed a normal motion. Apart from a little suppuration at the lower part of the skin wound the child made an uneventful recovery. On December 6, 1924, round worm ova were found in the fæces. On December 7, 1924, carbon tetrachloride (♏ vii) was given to remove any hookworm that might be present.

Before the child left hospital santonine and oil of chenopodium were administered, but no round worms were passed. She left hospital on January 15 perfectly well.

Case 3.—A Sinhalese lady, aged 34, was admitted into the Lady Havelock Hospital on October 3, 1924, giving a history that she was 10 months pregnant and had no signs of labour pains. Breast signs were absent. She said she had amenorrhœa for 6 months and after that bleeding off and on for the last 4 months.

On admission a solid, hard, lobulated tumour was found filling up the lower abdomen and extending to a level one inch above the umbilicus on the left side. On the right and continuous with the tumour was a hard nodule.

She had three children, the youngest aged 10. Laparotomy was done the day after admission and a tumour consisting of six months' dead fœtus was removed with great difficulty, enclosed in a sac formed by the layers of the broad ligament. Omentum and bowel were firmly adherent, which made the operation exceedingly difficult. As it was impossible to separate the tumour from the uterus a subtotal hysterectomy was done—the tumour being firmly attached to the left side of uterus. The nodule that was felt abdominally was the fundus of the uterus. Remains of the tube and ovary were found on the upper surface of the tumour. This, then, had been a case of tubal gestation with extra-peritoneal rupture between the layers of the broad ligament, i.e., an intraligamentary rupture with survival of the fœtus up to six months. Death of the fœtus took place four months previous to admission, and this corresponded to the time the bleeding started from the uterus. Apart from the presence of a tumour the patient suffered no discomfort. The wound healed up by first intention, and the patient was discharged from hospital three weeks after admission, getting very well.

Case 4.—Seeman (Sinhalese), aged 6, was admitted to the Children's Hospital on October 23, 1924, having been brought in a bullock cart from a village thirteen miles north of Colombo, with a history of having had fever for eight days and abdominal pain for three days. On admission his pulse was 120, and temperature 101·4° F., abdomen was very distended, rigid and tender all over. Bowels had not moved for two or three days and an enema was given with a "pea-soupy" result on the morning of October 24, 1924, pulse was 98 and temperature 97·8° F., and abdomen was still tender and rigid. By 2 p.m. pulse was 120, and the patient was crying out with abdominal pain. Laparotomy was done immediately and the abdomen was found to be full of pus Intestine was examined carefully and fæces were found oozing out of an aperture surrounded by a red area in the ilium about three inches above the iliocæcal valve. The aperture was quickly closed with a purse-string silk suture. The abdominal cavity was swabbed out as dry as possible and drainage tubes were inserted into Douglas' pouch and the right and left iliac fossa. Abdomen was closed, except lower end for the tubes, and the patient was nursed in the Fowler position. Saline glucose and soda bicarb. were given four-hourly per rectum.

October 27, 1924, blood was sent for Widal examination and the result was 1/40 positive, 1/80 negative. Temperature was normal and continued so. The wound discharged freely and rubber drainage was not got rid of till November 13, 1924. The patient progressed favourably, and the abdomen wound healed without any complication. The child was circumcised and discharged fit from the hospital on December 11, 1924.

Stovarsol in Amœbiasis, by Dr. Frank Grenier, Senior Physician, General Hospital, Colombo.

It has long been recognized that infections with *Entamœba histolytica* once established are remarkably persistent. Spontaneous disappearance of the parasites has never been proved to occur, and many cases are known in which an affection has lasted for years—certainly for 16 years—and probably for much longer periods.

The results of treatment of these refractory cases of chronic amœbic dysentery, and of chronic non-dysenteric amœbiasis have often proved disappointing. The experience of recent years, and the knowledge gained by systematic examination of stools in chronic amœbiasis have shown how this condition may clinically simulate sprue, and that its symptomatology, apart from dysenteric manifestations, is very complex and may imitate almost any gastro-intestinal disturbance, and that it is responsible for much chronic invalidism in the tropics.

Neither emetine nor emetine-bismuth iodide, nor the newer preparation, emetine periodide, are specific cures for amœbiasis. They are valuable drugs, but they do not always eradicate the infection or prevent relapses. For the incurable residue other methods of treatment had to be advised. Workers in France some years ago had recommended salvarsan in the treatment of these cases, but such treatment did not enjoy a long vogue.

In 1923 Professor Marchoux, of the Pasteur Institute, having observed the good effects of stovarsol given by the mouth in syphilis was stimulated to try it in amœbic dysentery. In his first case thus treated the cysts of *Entamœba histolytica*, which had persisted after a course of emetine, rapidly disappeared, and success was equally remarkable in chronic cases of amœbic dysentery.

Stovarsol or oxyaminophenylarsenic acid is but slightly toxic, easy to take, and after an extended use I have not observed any detrimental effect which can be attributed to the drug.

Report of some cases of chronic amœbiasis treated in hospital during the year with stovarsol:—

Case 1.—F.W., Burgher, dysentery, 10 years ago. Mother died of sprue. During last two years has been treated for sprue, sore tongue, and morning diarrhœa, bulky, pale, frothy stools, emaciation. While in hospital undergoing treatment for sprue—parathyroid and calcium and diet—his stools were daily examined. On the 11th examination typical cysts were found. A regular course of stovarsol was prescribed and continued after discharge. Patient improved rapidly, is now doing a full day's work and on practically ordinary diet, and repeated examination of fæces has been negative.

As regards the resemblance of chronic amœbiasis to sprue, I may quote the views of Acton and Knowles, of the Calcutta School of Tropical Medicine:—"Whilst sprue appears to be a clinical entity, may not it be the end phase of several different infections, e.g., with the Flexner bacillus, or after chronic amœbic dysentery associated with pancreatic and parathyroid deficiency?"

Case 2.—Recurring dysentery of two years' duration. In spite of several courses of emetine, intravenous salvarsan, colonic irrigations, &c., the condition tended to relapse. Rapid improvement under stovarsol and restoration to normal health.

This patient was a municipal employee, and the municipal bacteriologist informs me that repeated examinations of the fæces have given a negative result and that, moreover, a very chronic dermatitis the patient had had disappeared. These skin conditions are met with in amœbiasis, and are probably due to secondary streptococcal lesions in the bowel and absorption of "pressor" bases.

Case 3.—Recurring dysentery of 5 years' duration. Attacks every 3 or 4 months—an assistant at the Bacteriological Institute. Cysts could always be demonstrated in his fæces. Treated with stovarsol. Numerous repeated examination of stools now "negative." No recurrence for nearly one year.

Case 4.—Female. Dysentery 10 years ago. Recurring attacks of diarrhœa, last 6 months persistent diarrhœa. On admission extreme emaciation, hectic fever, prostration, a "living skeleton." Condition thought to be either sprue or abdominal tuberculosis. On eighth examination of fæces, cysts found. Improvement, though slow, was sure, and patient, who has been recently, had put on weight and was free of symptoms. This case treated with "yatren," and not stovarsol.

Case 5.—European male. Complained of dyspepsia and had symptoms of neurasthenia. Illness of 6 years' duration and dated back to war service in Egypt. Referred to his condition as "Egyptian Tummy." This case was one of chronic amœbiasis, where marked constipation, rather than diarrhœa was a symptom. Cysts found. Improved, and now in good health.

Case 6.—Female, English. Ill for 4 years with "colitis." Appendix removed last year, no benefit from operation. This case is illustrative of the fact that chronic amœbiasis may give rise to symptoms and signs of chronic appendicitis. Patient improved, stools became normal in character and frequency and were, on repeated examinations, "negative" for cysts. However, for a considerable time the patient's general health remained poor, and she manifested symptoms characteristic of the "confirmed abdominal neurasthenic," the condition being probably due to endocrine deficiency, the result of chronic intestinal sepsis. Many such cases of chronic amœbiasis finally drift into the "chronic abdominal type." One such case after "suffering many things at the hands of many physicians" finally received salvation and restoration to health from Christian Science. I may mention that in a recent case of chronic amœbiasis with symptoms of chronic appendicitis, the appendix was removed and numerous active motile amœbæ were found in the appendix, which was thickened and showed signs of chronic inflammation.

The Misuse of Emetine.—Whilst emetine is a most powerful drug, it is not sufficiently realized that it is a powerful cardiac and central nervous system depressant. The emetine is often given without justification for its use, often on the mere strength of symptoms of hepatic or intestinal disorder, and is to be deprecated. I have personally known of two cases of fatal cardiac failure from overdosing with emetine.

Stovarsal in Acute Amœbic Dysentery.—I have not given stovarsol a trial in cases of acute dysentery. It is the practice of some French medical men to give a continued course of emetine and stovarsol. It is claimed, however, that stovarsol is so efficient and so easy to give by the mouth that patients in private practice and those who cannot come often to hospital are treated with stovarsol alone.

Report of the Malariologist, Mr. H. F. Carter Scientific Section.—The information included in this section comprises brief summaries of certain investigations undertaken during the past year or more. The results of these and other investigations will be published in detail later, and will include a series of articles in the *Ceylon Journal of Science*.

Endemic Prevalence of Malaria in Ceylon.—The relative prevalence of malaria in different parts of the island was determined by spleen and blood examinations of random samples of children. The majority of these examinations were made in connection with a preliminary survey during the period July, 1921, to July, 1922, when, owing to limitations of staff and the extensiveness of the area involved it was not possible to synchronize the work with climatic conditions or to complete it within either of the monsoon periods. For these reasons the examinations were not in all cases strictly comparable, and factors—e.g., recoveries, relapses, &c.—influencing the rates were operating in varying degrees in different districts when the work was performed. The results of continued work in this connection, however, have not affected the figures given in the report for 1922 to any appreciable extent, and it may perhaps be justifiable to assume, therefore, that, as applied to the extensive areas mentioned, the findings afford a fairly reliable estimate of the

prevalence of the disease. Nevertheless, local and seasonal variations may be considerable and apparently are particularly liable to occur in areas of relatively low or moderate endemicity.

The endemicity of malaria varies considerably in different parts of the island, and that, in certain areas at least, such variations are coincident with changes in climatic and topographical conditions. Broadly speaking, the following areas of endemicity—as indicated by the spleen rate—may be distinguished.

Splenic Values.—The determination of the spleen rate (of children from 2 to 10 years of age), although of great practical value as a means of measuring the amount of malaria present in any given district, does not afford a true indication of the intensity of the disease, since the exact signification of the rate is unknown. When, however, the size of the enlarged spleen is observed, more valuable and precise information at once becomes available, as it has been shown that a definite mathematical relationship exists between the size of the spleen and the spleen rate. The proportions of the different classes of spleens change regularly with the spleen rate, ensuring for individual rates a comparatively stable formula. The latter, however, may be considerably influenced by certain factors, e.g., non-representation of the community examined particularly in regard to the inclusion in communities with low spleen rates of children from highly malarious districts, or the presence of some other disease productive of severe splenomegaly; and when such are present the proportions of the different classes of spleens may be at complete variance with those for the observed spleen rate.

The changes in the spleen composition (exclusive of obvious discrepancies) correspond fairly closely with those found by Christophers in India and Mesopotamia, although there appears to be a definite decrease in the proportions of large-sized spleens for each group of spleen rates.

According to Christophers a *splen* is the mean increase in splenic substance resulting from a single infection (untreated) in a child 2 to 10 years of age, and the number of *splens* distributed is a direct measure of the intensity of malarial infection. The value of the *splen* being known the latter may easily be calculated, and from this the spleen rate corresponding to the spleen composition may be obtained. The average values of the *splen* in India and Mesopotamia have been determined at 90 and 114 grm., respectively, while that for Ceylon—owing to the difference in size of enlarged spleens—is less, being approximately 80 grm.

The Relative Prevalence of the Different Species of Malarial Parasites.—The results of examinations show that in every district the benign forms (benign tertian and quartan) of malaria predominate; malignant or subtertian malaria appears to be relatively uncommon, averaging only slightly over 10 per cent. of all infections observed. The figures now given differ in several respects, especially in regard to the relative prevalence of quartan malaria, from those in the report for 1922; but all such discrepancies are evidently due to the comparatively small numbers of "positive" films which were available for analysis at that time.

The relative scarcity of malignant malaria in Ceylon is a matter of considerable interest and importance, since in most tropical countries this form of the disease preponderates, and is concomitant with a high prevalence of pernicious cases and severe mortality. It is, moreover, considered by some authorities that the parasite (*Plasmodium falciparum*) responsible for this form of malaria is the chief causal factor of blackwater fever, and that the presence of this organism in a high portion of infections is necessary for the production of this condition. If this view be correct, the almost complete absence of blackwater fever from Ceylon —even from those districts where malaria is hyperendemic—may readily be explained by the results shown. It is very probable, however, that the percentage proportions of the various species of parasites in the different areas are subject to seasonal fluctuations, and that at certain times any one species may become more prevalent; but the evidence at present available indicates that in the case of malignant malaria a widespread increase sufficiently great to render it the predominating form is not a common occurrence.

The Differential Characters of the Indigenous Anopheline Mosquitoes in their Adult and Larval Stages.—Fifteen species, and their varieties, of anopheles have now been found in Ceylon. Of these, nine are abundant, including two (*A. maculatus* and *A. gigas*) which are confined to the hill country. In the low country, although the same species occur in both the wet and the dry zones, they are present in very different proportions. In the wet zone *A. listoni* and *A. culicifacies* are relatively uncommon, and are, to a great extent, replaced by the comparatively innocuous swamp-breeding species, *A. jamesi*, *A. hyrcanus* and *A. barbirostris*. Proceeding from the wet zone to the dry zone districts, the proportions of the various species gradually change, those of *A. subpictus*, *A. listoni*, *A. culicifacies* and *A. fuliginosus* being increased, while those of the "swamp breeders" mentioned above are correspondingly reduced. It would appear probable that this change in the composition of the anopheline fauna is a factor of fundamental importance in connection with the relative freedom of the low country wet zone (i.e., the south-west portion of Ceylon) from malaria and it is of interest to note that in several instances (e.g., Mutwal, 1903; Mahara Jail, 1922; Dematagoda, 1923) during recent years when localized epidemics have occurred in this part of the country, conditions have been present which especially favoured the propagation of *A. culicifacies* or *A. listoni*.

The more important distinguishing characters of the adults and mature larvæ of the indigenous anopheles are summarized in the following tables:—

Synopsis of Adults.

(1) Wing entirely dark, or the upper margin with not more than three pale spots; cross-veins and bases of forks of veins dark (subgenus *Anopheles*).

Wings with at least four pale spots on the upper

margin; cross-veins and bases of forks of veins pale (subgenus *Myzomyia*).

(2) Wings without pale spots; uniformly brown in colour (*aitken* James).

Wings with light and dark spots.

(3) Wings with three pale spots on the upper margin, the markings sharply defined; large species (*gigas* Giles).

Wings with at most two pale spots on the upper margin, the markings not sharply defined; medium sized or large species.

(4) Hind legs with a dense tuft (black and white) of outstanding scales on the femora (*annandalei* Pras.).

Hind legs normal without a tuft of outstanding scales.

(5) Femora, tibiæ and first tarsal segments of all the legs conspicuously spotted with yellow (*pseudo-barbirostris* Lud.).

Femora, tibiæ and first tarsal segments with pale spots at their extremities only.

(6) Palpi in female entirely black, shaggily scaled, in male black with an indistinct ring on the proximal portion; wings with black and white scales, the black preponderating; large blackish species (*barbirostris* Wulp).

Palpi in female with narrow pale rings, in male with distinct rings and the apex of the club white, wings with black and yellow scales, the yellow preponderating on the lower portion of the wing; medium-sized to large, dark brown species (*hyrcanus* Pall.).

(7) Femora and tibiæ with pale spots at or near their extremities only.

Femora and tibiæ conspicuously spotted throughout with white or yellow.

(8) Tarsal segments of all the legs entirely dark.

Tarsal segments with distinct pale rings.

(9) Thorax brown; palpi in female with three narrow widely separated rings, in male with pale rings, the club mainly dark scaled; base of first vein mainly black, fringe dark or with one or two indistinct pale spots (*culicifacies* Giles).

Thorax mainly gray; palpi in female with three pale rings, the two terminal ones broad and narrowly separated, in the male with pale rings, the club mainly yellowish; base of first vein yellow, fringe with several conspicuous pale spots.

(10) Proboscis entirely dark, sometimes paler beneath the apical half; fringe without a pale spot opposite the sixth vein (*funestus* var. *listoni* List.).

Proboscis conspicuously pale (golden) on the apical half; fringe with a pale spot opposite the sixth vein (*funestus* var. *aconitus* Don.).

(11) Tips of the hind legs dark; pale bands on tarsal segments of fore legs broader than those on the hind legs.

At least the tips of the hind legs white; pale bands on tarsal segments of fore legs, narrower and less conspicuous than those on the hind legs.

(12) Palpi in female with three pale rings, the apical ring not more than 1½ times the length of the adjoining black band; proboscis uniformly dark; fringe usually with an extra pale spot between the fifth and sixth veins; tibiæ and first tarsal segments with conspicuous longitudinal striping (*subpictus* Grassi).

Palpi in female with three pale rings, the apical ring very broad, at least 3 times the length of the adjoining band; proboscis in female with a pale area before the apex; fringe usually without a pale spot between the fifth and sixth veins; tibiæ and first tarsal segments without pronounced striping (*subpictus* var. *vagus* Don.).

(13) Hind legs with the last three tarsal segments entirely white; palpi in female with three white rings (*fuliginosus* Giles).

Hind legs with the tip (last segment) only white; palpi in female with four white rings (*karwari* James).

(14) Pale markings on the second to sixth veins extensive; often forming relatively large bars; sixth vein with not more than three dark spots.

Pale markings on the second to sixth veins interrupted by very numerous small black spots; sixth vein with at least four dark spots.

(15) Hind legs with the last three tarsal segments entirely white; palpi in female with three white rings the second narrow and widely separated from the apical ring (*jamesi* Theob.).

Hind legs with the tip (last segment) only white; palpi in female with three white rings, the apical ones broad and narrowly separated (*maculatus* Theob.).

(16) Hind legs with a very broad white band covering the tibiotarsal joint (*leucosphyrus* Don.).

Hind legs without such a band (*punctulatus* var. *tessellatus* Theob.).

Synopsis of the Mature Larvæ.

(1) Shaft of antenna with a branched hair, or if absent the post-antennal hairs short and inconspicuous. (Subgenus *Anopheles*.) Shaft of antenna without a branched hair, the post-antennal hairs always long and conspicuous. (Subgenus *Myzomyia*.)

(2) Shaft of antenna without a branched hair, post-antennal hairs small; thorax and abdomen completely covered with minute curved setæ (*annandalei* Pras.).

Shaft of antenna with a branched hair, post-antennal hairs large; thorax and abdomen without setæ.

(3) Outer clypeal hairs with a few short branches, or simple; hair on antenna arising near base of shaft.

Outer clypeal hairs thickly branched dendriform; hair on antenna arising near middle of shaft.

(4) Thoracic palmate hair vestigial with four or five hair-like divisions; abdominal palmate hairs with leaflets terminating bluntly; large species (7 mm.) (*gigas* Giles).

Thoracic palmate hair well-defined with several (10-14) narrow leaflets; abdominal palmate hairs with leaflets terminating in definite filaments or very sharp points; small species (3·5 mm.).

Colonial Medical Reports.—No. 193.—Ceylon (*continued*).

(5) Inner and outer clypeal hairs branched, the former usually bifurcating before the middle (*aitkeni* James).

Inner and outer clypeal hairs simple (*aitkeni* var. *insulæflorum* Swel.).

(6) Innermost submedian anterior thoracic hairs branched (6·8 divisions) from or near the base; black with white markings (*barbirostris* Wulp).

Innermost submedian anterior thoracic hairs simple, or with two or three very short branches arising on the distal portion of the stem; yellowish-green or yellowish-brown without definite white markings (*hyrcanus* Pall.).

(7) Abdominal tergal plates very large, occupying from nearly one-half (first segment) to almost the whole (eighth segment) of the dorsal surface of the segments.

Abdominal tergal plates smaller, those on the anterior segments reduced to narrow transverse bars.

(8) Inner and outer clypeal and pre-antennal hairs simple, or (intermediate form) with a few short branches, those on the pre-antennal hairs arising at intervals along the stem (*funestus* var. *listoni* List.).

Inner and outer clypeal hairs with more numerous short branches, pre-antennal hair branched (5 or 6 divisions) from the base (*funestus* var. *aconitus* Don.).

(9) Outer clypeal hairs simple, or with a few short branches only; pre-antennal hairs simple, or with faint lateral branching.

Outer clypeal hairs thickly branched, plumose; pre-antennal hairs branched, usually from the base.

(10) Inner and outer clypeal hairs simple, or the inner only with fine, short, lateral branches; thoracic palmate hair (except *A. subpictus*) small, but with definite leaflets.

Inner and outer clypeal hairs with short lateral branches; thoracic palmate hair with hair-like divisions only.

(11) Anterior clypeal and pre-antennal hairs always simple; leaflets of abdominal palmate hairs ending in long filaments.

Inner clypeal hairs usually with short branches; leaflets of abdominal palmate hairs ending in blunt points.

(12) Thoracic palmate hair vestigial, with long hair-like branches; submedian thoracic hairs scarcely pigmented, the innermost without a conspicuous dark root; antennæ feebly chitinized, unpigmented.

Thoracic palmate hair small, but with six to eight short leaflets; submedian thoracic hairs powerful, pigmented, the innermost with a conspicuous dark root; antennæ strongly chitinized, the tips dark (*culicifacies* Giles).

(13) Pre-antennal hairs situated below or outside the inner clypeal hairs; outer clypeal hair long—from $\frac{2}{3}$ to $\frac{3}{4}$ the length of the inner (*subpictus* Grassi).

Pre-antennal hairs situated between the inner clypeal hairs; outer clypeal hair very short—$\frac{1}{4}$ or less the strength of the inner (*subpictus* var. *vagus* Don.).

(14) Innermost submedian anterior thoracic hairs short, with two or three branches (occasionally simple) without conspicuous roots (*punctulatus* var. *tessellatus* Theob.).

Innermost submedian anterior thoracic hairs large with numerous branches and conspicuous roots (*leucosphyrus* Don.).

(15) Extremities of leaflets of abdominal palmate hairs sharply pointed or filamentous (*maculatus* Theob.).

Extremities of leaflets of abdominal palmate hairs bluntly pointed (*karwari* James).

(16) Vertical clypeal hair long and simple, occasionally bifid; leaflets of palmate hair on first abdominal segment very narrow, usually hair-like, 7-8 in number (*jamesi* Theob.).

Vertical clypeal hair short, with four or five branches arising, usually, from the base; leaflets of palmate hair on first abdominal segment differentiated, 10-12 in number (*fuliginosus* Giles).

The Relation of Paddy Cultivation to Malarial Endemicity.—Investigations in this connection were conducted at several towns situated in different parts of the island with a view to determining the effects of varying conditions upon the anopheline fauna of the rice fields, and the relation of the latter to the incidence of malaria; they were commenced in August, 1922, and continued until November, 1924. The area under paddy at the centres selected considerably—from approximately thirty to several hundred acres. At each centre from ten to thirty fields (varying in total area from one to three acres), situated in three or more blocks in different parts of the town were selected, mainly in accordance with their position in relation to dwellings and irrigation channels.

Examinations for anopheles larvæ were made each month; they were not restricted to the rice fields alone, but included uncultivated fields, irrigation channels, swampy areas and pools produced by seepage, and various other types of potential breeding places in the vicinity.

Except in the wet zone the predominating species of anopheles breeding in the rice fields are *A. subpictus* and *A. hyrcanus*, but the more effective malaria transmitting species—*A. listoni*, *A. culicifacies* and *A. maculatus*—when taken together form an appreciable percentage of the anopheles fauna.

In many parts of the island it would appear at first sight that the irrigation channels themselves are more important factors in the production of malaria than the rice fields, but it is necessary to observe that the total prevalence of anopheline larvæ of all kinds in the channels is in general considerably less than in the rice fields—a fact which, in practice, may tend to equalize matters. It has yet to be determined, however, whether the larvæ of the more important species occurring in the fields are derived primarily from the irrigation

channels or exactly to what extent lack of control of the water supply is responsible for their propagation. Evidence is available which shows that the paludic conditions invariably associated with irrigation are seriously conducive to anophelism of a dangerous type, and that much stricter control—particularly of the privately owned channels—will be necessary if the incidence of malaria is to be reduced.

The average prevalence of the various species of anopheles in the rice fields vary to a greater or less extent in the different areas, chiefly according to the stage of cultivation and growth of the crop. The most definite change is in regard to the species *A. subpictus* and *A. hyrcanus*. Usually, during the early stages of cultivation when there is little or no growth and the water is stagnant and muddy, the predominant species is *A. subpictus*, but in most districts *A. hyrcanus* becomes more prevalent as the growth of vegetation increases, reaching its maximum abundance when the crop is sufficiently tall to shade the surface of the water. No very definite variations in the prevalence of the malaria-carrying species have so far been observed.

Colonial Medical Reports.—No. 194.—Egypt.

ANNUAL REPORT ON THE WORK OF THE PUBLIC HEALTH DEPARTMENT FOR 1922.

Vital Statistics.

The birth-rate for 1922 was 43·2 per thousand, as compared with 42·3 for 1921, and the death-rate was 25·2 per thousand, as compared with 25·3 for 1921.

Kasr el 'Aini Hospital.

Kasr el 'Aini Hospital.—The number of in-patients admitted during the year was 13,074. There was a continuous increase in the number of in-patients admitted in the hospital during the last five years. The death-rate of in-patients in 1922 was 8·35 per cent., as against 9·13 in 1921. The number of out-patients was 122,416, the number of attendances being 353,251.

Encephalitis Lethargica.—13 cases of this disease were admitted during the year as against 3 in 1921. 2 of the cases were of the myoclonic type, and 1 of the cerebellar type. Several cases presented a clinical picture closely simulating paralysis agitans.

Lithotrity versus Suprapubic Lithotomy.—During 1922 51 cases of vesical calculus were treated by lithotrity with 7 deaths. 6 of the 7 cases that died showed, post-mortem, advanced cystitis and pyelonephritis. In the remaining case no definite cause of death was discovered. In none of the 7 cases was there a rupture of the bladder. This mortality compares very unfavourably with statistics of 815 cases done by Freyer on adult males with a mortality of 3·06 per cent.

The mortality from suprapubic lithotomy during 1922 was 10·81 per cent. in 37 cases. The above facts suggest that cases with septic urinary passages stand lithotrity worse than they do suprapubic lithotomy. This, however, is a disputed question and well worth further and more thorough investigation.

Splenectomy.—12 splenectomies were done for endemic splenomegaly during the year. Of these 2 died in hospital. One, two and a half months after operation; post-mortem of the liver showed advanced cirrhosis. The other died of broncho-pneumonia on the third day of the operation. He, too, had advanced cirrhosis of the liver.

8 cases of ruptured spleen were admitted during the year. 5 died before and 3 after operation. 2 of the 8 cases had rupture of the liver as well. The remaining 6 cases had enlarged spleens (malarial or otherwise), hence the high mortality.

Tetanus.—Both the incidence and mortality of tetanus were higher during 1922 than the previous year. Of 16 cases admitted 12 died—a mortality of 75 per cent. Of the 4 cases that recovered, 2 had an incubation period of 17 days and 32 days respectively. The other 2 had no wounds or history of wounds so that the incubation periods could not be ascertained. Of the 12 cases that died 3 had an incubation period of 2 days, 5 days and 10 days respectively; 2 had recent wounds, but the exact time of infliction could not be ascertained. The other 7 cases had no wounds or recent scars, so that, there again, the incubation period could not be estimated.

Hydrophobia.—In spite of an increase in the number of antirabic cases, the number of cases of hydrophobia has decreased.

Of 7 cases of hydrophobia in which the site of the bite was known, in 6 this was the face and in 1 the forearm. Of 11 cases of hydrophobia 6 had no prophylactic treatment and 5 had a complete course.

Ankylostomiasis.—During the past year trial was made of two new anthelmintics for ankylostomiasis namely, carvacrol and carbon tetrachloride. The former drug is a fluid isomer of thymol and, it was thought, might be effective in smaller doses, on account of its liquid character. The results showed that, to be effective, the drug required to be given in about the same amount as thymol (dose 3 c.c.) and did not appear to possess any special advantages.

Carbon tetrachloride was only introduced this last year and investigations were begun before clinical reports on its own use were published. Those now available show that the doses used have been 3 c.c. alone or 5 c.c. with castor-oil. These doses have no toxic action on the liver, and act well without preliminary preparation of the patient.

Our experience at Kasr el 'Aini, so far, is in favour of large doses; a single dose of 3 c.c. being much less efficacious. Excellent results have followed the administration of 6 to 8 c.c. of carbon tetrachloride mixed with about the same quantity of castor-oil, given in two halves at 2 hours interval. Greater dilutions than 1 in 3 of the drug reduce its efficiency. As large a dose as 10 c.c. has been given with no ill-effect, but it must be remembered that the combination with castor-oil minimises absorption.

The drug appears to have a strong bactericidal as well as vermicidal effect. The results obtained compare favourably with those of chenopodium and thymol, and are naturally most striking when a large number of worms are present.

More work is in progress to determine the most effective and economical method of using the drug on a large scale, since it appears a safer and more powerful anthelmintic than those hitherto employed. For this purpose a special annexe has been prepared at Port Said.

Auricular Fibrillation.—Quinine sulphate was tried in 12 cases showing this condition. The diagnosis was made on clinical grounds. 0·040 grm. in tabloid form was given by mouth three times a day. In no case was the fibrillation stopped. The pulse-rate was reduced and the irregularity diminished, but with no obvious advantage. Nausea and vomiting were induced in the majority of the cases.

Bilharziasis.—Oral administration of tartar emetic was tried in 6 cases. Enteric coated pills, each containing 0·06 grm. tartar emetic, were given twice a day. In only one case was the urine reported negative after a course of 20 pills. In another case 40 pills were given, but with no effect. In 4 cases treatment had to be stopped after a few days on account of the onset of vomiting, diarrhœa and colicky pains.

Rectal administration of tartar emetic was tried in 13 cases. The method of administration was as follows: a mild laxative was given at night and in the morning an enema of 100 c.c. distilled water containing the dose of tartar emetic required with 8 mm. tinct. opii. was given with a funnel attached to a soft rubber catheter. Enemata were retained for periods between 8 and 24 hours. 6 gr. of tartar emetic were given to begin with, increasing by 2 gr. each time. The enemata were given every other day. The rectal administration of tartar emetic is far inferior to the intravenous method. A combination of tartar emetic and emetine was found more effective in the treatment of intestinal bilharziasis than either drug used alone. Bismuth was tried chiefly as a possible substitute for antimony in the treatment of bilharziasis. The compound used was the liquor bismuth et ammonii citratis (B.P.) sterilized for intravenous use. Subcutaneous or intramuscular injections proved to be irritating and unsuitable. The results were that slight chronic infections were cured, but an attempt to use larger doses than 1 c.c. (for the treatment of more active infections) was abandoned owing to the development of toxic symptoms. Meanwhile research in France on the action of bismuth in syphilis and spirochætal infections showed that preparations of this metal were ten times as toxic when administered intravenously as when given by intramuscular injection. Further, by suspending soluble bismuth compounds in an oily vehicle, the irritating properties were overcome. Such compounds are now being tried; the double tartrate can now be bought. The employment of intravenous injection in almost toxic doses revealed an extraordinary effect on the kidneys and renal excretion resulting in a striking diuresis. This effect was studied and reported in the *Lancet*, August 12, 1922, page 328.

Cancer.—The use of diathermy for malignant conditions has, for some time, been recognized as efficacious. It was used in the surgical unit as a routine, both for the cure of superficial conditions and to replace the knife in all operations on cancer and sarcoma. Of 8 cases done during the last three months, 2 were discharged apparently cured. Cancer immunization has so far been done in 37 cases with some promising results. The difficulty of establishing a follow-up system, however, robs this method of treatment, as any other, of much of its value. The use of amniotic fluid in the treatment of inoperable cancer is also under investigation. It has been tried in 5 cases. These are still under treatment.

Milk Injections.—2 cases of undoubted septicæmia were treated with milk injections. Both cases were cured. 2 cases of inoperable carcinoma have also been treated in the same way, but further investigation is still necessary for arriving at any conclusions.

Blood Transfusion.—Blood transfusion in regard to deficiency diseases is now on its trial. A suggestive field has been opened by the complete restoration of carbohydrate tolerance for 21 days in a case of diabetes mellitus following the transfusion of whole blood.

Vasectomy for Senility.—This promises to enable the helpless aged poor to earn at least a partial livelihood. Unilateral vasectomy in cases of senility and debility without gross organic disease has been performed 17 times with encouraging results. In 1 case of senile chorea marked amelioration of symptoms was effected. Photographic records of patients are being carefully kept.

Butyn.—Butyn is a substitute for cocaine as a local anæsthetic. It has the following advantages over cocaine:—

(1) It is more powerful and acts more rapidly, and over a longer period than cocaine.

(2) *In the quantity required*, it is less poisonous than cocaine, and its cost is very little greater.

(3) It does not produce the same intoxicating

effect on the central nervous system and consequently does not possess attractions for the drug-taker. After employing it for a period of three months in close on 100 operation cases, it was found to be extraordinarily effective as an anæsthetic, either dropped locally into the eye, or in infiltration-anæsthesia. No toxic results had so far been noticed. A 2 p.c. solution has been used, 10 cubic centimetres of which cost P.T. .5·6 as compared with P.T. 5·2 for a 5 p.c. solution of cocaine hydrochloride, which is less effective as a local anæsthetic in ophthalmic work. Also smaller quantities of the solution were used in each case, so that the cost may actually be less than in the case of cocaine.

Anthelminthic Section.

The number of new cases sent to the section during 1922 was nearly one and a half times that of 1921. Of the total number about 12 per cent. are females and 20 per cent. children under 12.

About 20 per cent. of the patients sent to the section showed a negative result for helminthic infection on examination of the dejecta. Of the 80 per cent. positive cases, half the number completed the full course for bilharziasis and the other half received less than 10 injections. More or less irregularity in attendance is noticed in the majority of patients. The most regular in attendance are the children and women: of the men employees and students, specially those of El Azhar, are the best.

Bilharzia Division.

Specimens are collected for examination the first day of attendance and the treatment started the next day when the results are known. Negative cases which have symptoms and signs of other diseases, e.g., cystitis, or, in the case of intestinal disease, amœbic infection, are given appropriate treatment. As a routine measure, a re-examination of the dejecta is made at the time the penultimate injection (the eleventh) is given, and the result recorded. Should living ova still be found, extra injections are given—usually three—and the result again ascertained.

About 24 per cent. of the cases are unsuitable, i.e., show no ova or have severe cystitis which requires treatment before any underlying bilharzial infection can be safely dealt with. The ordinary course was sufficient in all but 0·5 per cent. Examination of the patients returning three to four months after a satisfactory course showed a complete cure had been obtained.

Drugs.—No difference was found between the sodium and the potassium antimony tartrate as regards their effect on the ova. For the patient the sodium salt is less toxic; vomiting and coughing are less than with the potassium compound. Also the sodium salt appears less irritative to the subcutaneous tissues, so that in some cases of escape from the vein very little inflammation followed and usually subsided under fomentations. In a few instances a sterile abscess was evacuated with a syringe. Nocturnal enuresis in children is sometimes an early sign of bilharziasis. Such cases were cured by antimony treatment. 1 case of cutaneous leishmaniasis in a girl was sent for treatment. The condition improved after 4 injections, when the patient ceased attendance, so that the effect of a prolonged course could not be ascertained.

Complications.—Cough and sometimes vomiting are the usual immediate toxic effects. Sometimes bleeding occurs from the strain; this is readily checked by rest and giving ice to suck.

One Death Occurred.—This was a girl of 14, who had received 8 injections without any symptoms. After the ninth she coughed a while and then felt better. She left the tent in a good condition, but in the same afternoon was brought to the hospital in a collapsed condition and died that night.

An epileptic boy was seized with a fit every time he was given an injection. He was admitted into hospital.

Emetine.—This drug is used for subcutaneous injection in children whose veins are too small for intravenous injections. In consequence of the claim made by a local doctor and published in a foreign journal of repute, that a daily dose of emetine (the maximum being 2 gr.) continued for 12 days will certainly cure bilharziasis without the development of toxic symptoms, this course was given to 2 adult men and a woman. The hæmaturia disappeared after 6 injections, but there were many living and few dead ova on examination of the urine. After the tenth injection a considerable proportion of living ova were still present, and following the next injection the patients complained of numbness in their hands and legs. This result confirmed all the hospital's previous work that it is not possible to shorten treatment if we aim at a cure and not a mere amelioration of an obvious symptom.

Bismuth.—Under treatment with soluble compounds of bismuth some mild cases of bilharziasis were cured, the ova being killed. More active infections were much less affected, and at present it does not seem that bismuth is a satisfactory substitute for antimony in this disease.

Ankylostoma Division.

1,241 patients were sent to the section for treatment under the tentative diagnosis of ankylostomiasis. The stools were examined on the first day of attendance.

The flotation method was employed in examination except in the case of liquid and blood-stained stools. The ankylostoma patients are the most unsatisfactory in their attendance. When possible anthelminthic treatment is given at their first visit, but this is often impossible owing to the late hour of arrival or the fact that they have recently had bad food. Such cases were told to come early the next morning fasting, but often the patients never returned.

Colonial Medical Reports.—No. 194.—Egypt (*continued*).

It is customary to give one treatment to negative cases and 2 or 3 to positive cases of ankylostomiasis; other infections receive appropriate treatment. The hæmoglobin and pulse-rate of every patient are determined before a vermicide is given. A marked rise is noticed in the hæmoglobin value under treatment when the worms are expelled, as is shown by the absence of ova in the stools on subsequent examination. Patients sent to the bilharzia division who are anæmic are not given the antimony course until their condition is improved by the expulsion of ankylostomes and the administration of hæmatinics.

Drugs.—Oil of chenopodium was almost the only drug used as a vermicide. It is put up in capsules of 0·5 c.c. Adults were given 4 capsules (2 c.c.) children 3 capsules, followed by a purge. Santonin and male fern are given for ascaris and tænia, respectively. Carbon tetrachloride is now under trial. At first it was given in doses of 6 c.c. (adult) or 4 c.c. (child) mixed with an equal dose of castor-oil. It is now being given pure in doses of 4 c.c. and 3 c.c. (children).

Alexandria Government Hospital.

General.

6,948 patients were admitted to the hospital, 5,562 males and 1,386 females. This is a decrease of 1,312 cases less than the number of admissions during the year 1921. With the addition of 297 cases remaining at the end of the year 1921 to the total number of admissions, we get a total of in-patients 7,245.

While the admissions have decreased, the out-patient cases are more than doubled.

The following factors explain to a great extent the diminution in the total number of admissions during the year:—

(1) The number of beds of this hospital is at present too small for the city of Alexandria and the environments which naturally drain here. During past years extra cases were allowed to lie on the top floor or were accommodated on the balconies, but such arrangements were found impracticable and were stopped. If there had been more beds more cases could have been accepted and the admissions would have shown a big increase.

(2) The outbreak of infectious diseases during 1922 was the mildest ever known. There was no need to open the Chatby Isolation Hospital as all the cases we received were easily accommodated in the infectious block of the General Hospital.

(3) No military cases at all were dealt with during the past two years, while they used to increase the general number of the takings-in.

(4) Admissions to the *harim* were stopped early in December due to the new buildings.

The 6,948 admissions mentioned before do not include the women that received treatment at the Lock Hospital for native prostitutes (formerly the ex-Austro-Hungarian Hospital at Muharram Bey, and at present at Gabbary).

The Lock Hospital for Native Prostitutes.

918 cases received treatment at the Lock Hospital during the year, as compared with 914 during last year and 1,057 during 1920. With the addition of 44 cases remaining at the end of the year, the total is 962.

The Lock Hospital used to be the ex-Austro-Hungarian Hospital at Muharram Bey, and was evacuated on December 1, 1922, and the patients were subsequently moved to Gabbary.

The following table demonstrates the nature and results of treatment of these cases.

Diseases.	Cured.	Transferred to General Hospital.	Total.
Syphilis	234	—	234
Gonorrhœa	280	—	280
Soft sore	107	—	107
Skin diseases	19	—	19
Relatives accompanying patients	19	—	19
Under observation (found non-contagious)	253	6	259
Total	912	6	918

Summary.

Cases existing at beginning of 1922	38
Cases admitted during the year	924
Cases discharged during the year	918
Cases remaining at end of 1922	44

The Anthelmintic Annexe.

A Short Note on the Treatment of Bilharziasis and Ankylostomiasis.

Bilharziasis.

As in the year 1921, the out-patients annexe looked after the majority of the bilharzia cases; the severe, complicated and debilitated cases, however, as well as policemen, soldiers and *ghafirs*, municipality labourers, &c., together with those patients coming from distant places, especially the women, had to be admitted for treatment into the hospital wards.

The total number treated during the year 1922 is 405, as compared with 481 during the year 1921. The patient is given every other day an injection of the tartar emetic. As most of the intestinal cases are usually complicated by other secondary and dysenteric infections and exhausted by excessive bleeding and gastro-intestinal disturbances, they have to be treated in hospital, whilst urinary cases predominate in the out-patients. Patients of all ages attended, the average being 12 to 35 years. The youngest was a boy of 4 years.

Most of these cases present a category of diseases, especially of the parasitic affections, i.e., ankylostoma, pellagra and dysenteries with splenomegaly, hepatic cirrhosis, urinary fistulæ, restal papillomata and the complications of their advanced stages. 26 cases of the 101 in-patients had pellagra and 16 had amœbic dysentery. In spite of the treatment being regularly and comfortably given, many of the patients stopped attending either after the fifth injection, at a time when improvement sets in, or at the eighth, and is probably

due to the severe reaction or other external influences.

A special form has to be filled up for every new patient showing the history, past and present, age, sex, &c., and the microscopical findings with the progress of the treatment. The specimen, whether urine, stools, or both, is examined microscopically before starting the treatment, and this is repeated after the second week and after the third week, and then, as a confirmatory control, some 10 days after the end of the treatment. Tartar emetic still holds its first position. A sterile 6 per cent. solution in distilled water is prepared in hospital for stock use. The dosage varies with age and constitution. A ½ gr. is the usual initial dose, especially in youngsters, these being usually increased to a maximum of 2 gr. Improvement is apparent after the seventh grain, but an average total of 17 to 21 gr. is usually necessary for a real cure to be attained. 12 gr. have effected a cure in a boy of 8. Emetine has been used in very few cases with the special advantage of controlling bleeding in chronic advanced cases.

Nausea, vomiting, irritative cough, rigors, insomnia, pains all over the body, anorexia, wasting and debility, are the general reactions experienced by the patients. A sense of dysuria is also noted. Stomatitis and diarrhœa, in course of antimony treatment are signs of danger, especially in pellagrins. It may be interesting to note that, in a straightforward early case, the more reaction a patient suffers the better result he will enjoy.

Ankylostomiasis.

As in preceding years, all ankylostoma patients were admitted to the hospital and looked after in the medical wards. 56 patients were treated during the year 1922 and most of them required treatment for one or more concomitant disease. Oil of chenopodium is considered the best and most effective vermifuge and has always been given the preference to any other anthelmintic. Thymol had to be given on a few occasions, when the oil of chenopodium failed to give a satisfactory result. 3 c.c. of the oil given in 3 successive doses, at 2 hours interval, repeated on the fourth day and the eight, if necessary, was the usual routine dosage for an adult. Thymol to be given in doses from 1 to 3 or 4 grm. according to the age and constitution of the patient. There were no deaths at all, as, out of the 56 cases, 15 were completely cured, 35 were considered relieved, and 6 were discharged unrelieved, due to their refusal to stay long enough in hospital. No alarming symptoms ever appeared, in fact, no untoward symptoms beyond giddiness, epigastric discomfort and whistling in the ears. Any number of worms have been expelled on the first day of treatment, and it is interesting to note that other worms, especially the ascaris, which is a very common concomitant, used to be voided as well. It was a rule to purge the patient before and after the administration of the vermifuge and fast him in between. The stools passed during the next 24 hours were then collected, emulsified, strained with gauze and examined. Some cases, though negative microscopically, contained worms, and *vice versa*, other cases, positive under the microscope, could not be made to pass worms. The results of treatment were always saisfactory; the patients usually gained in hæmoglobin, added body weight and felt great improvement.

Poisonous Plants.

The transport in the country for export of poisonous plants, such as henbane, colocynth, datura, &c., is controlled as far as possible. Only one new authorization has been issued during the year. A considerable amount probably escapes detection as it is transported by river or caravan. The quantities which have been legally sent from Upper Egypt to the ports of embarkation are as follows: 688 kilos. of colocynth and 5·500 kilos. of henbane.

Opium.

As in the past the cultivation of the opium poppy and the collection of the opium is entirely uncontrolled; it is quite impossible to state the quantity produced or how it is disposed of. In order to exercise any effective control it would be necessary to know: (1) the quantity of seeds sown; (2) the total area planted; (3) the number of plants allowed to mature; (4) the quantity of opium collected; (5) the percentage of alkaloids which it contains. According to various analyses which have been made in the public health laboratories, it has been found that the morphia content varies from 3 per cent. and in some cases as much as 15 per cent. has been found. The strength depends to a large extent on the district in which the opium has been grown. The total quantity of opium imported during the year is 9,555 kg.; according to the registers of authorized poison dealers, this quantity has been re-exported to adjacent countries by sailing boats or by caravan. With regard to the opium produced in Egypt, it is known officially that 1,395 kg. have been transported under authorization, of which 665 kg. have been disposed of by authorized persons and 730 kg. by the cultivators on their own account.

STUPEFACIENT DRUGS (COCAINE, MORPHINE, HEROIN, DIONINE AND CANNABIS INDICA).

Although the new law has been successful to a certain extent in limiting the importation of stupefacient drugs for medicinal use to the actual needs of the country, it is certain that contraband traffic is still being carried on to an enormous extent.

Since 1920 the imports of cocaine have been steadily increasing every year; a fluctuation in the quantity of morphine increasing in 1921, and decreasing in 1922; an enormous increase in the quantities of heroin and dionine, namely, from 4 to 39 kg. and from 6 to 8 kg., respectively. Taking into consideration the large quantity of cocaine imported in 1922, namely, 155 kg., the figures show a large increase generally in the imports of the most

dangerous habit-forming drugs. It is to be regretted that the abuse of heroin and cocaine is facilitated by certain doctors over whom the pharmacy law has no jurisdiction. It is very probable that if steps could be taken to prevent these doctors writing prescriptions *ad libitum* for these drugs the consumption would decrease considerably.

Clinical Section.

Glaucoma.

The number of cases of primary glaucoma examined during the year 1922 was 2,512, or 1·7 per cent. of the total number of new patients presenting themselves for treatment. This number included 1,968 cases of absolute glaucoma in one or both eyes. The operation performed was usually Elliott's operation of trephining the corenosclera combined with iridectomy through the trephine hole; 503 operations were performed. In 466 operations, including those in which, owing to lenticular opacity, extraction would have to be performed sooner or later, iridectomies were performed. In the report for the year 1913 was mentioned: "the operation can and should be performed for a patient on an unaffected eye, as soon as the fellow eye has been definitely diagnosed as glaucomatous, since the operation is almost devoid of risk, and early operation is prophylactic against the development of increased tension, glaucoma usually affecting both eyes sooner or later." This policy has been religiously adhered to during the last ten years, and there is no reason to alter this opinion. Secondary infections are extremely rare in Egypt, only 17 cases having been reported since 1911 out of 5,017 operations of trephining performed during this period.

The extraordinary difference in the incidence of secondary infection between experiences in Egypt and the experience of some European surgeons must have its origin in one of four causes:—

(1) Defective inspection of post-operation cases in Egypt; the patients developing much more secondary infection than one has knowledge of, but refraining from presenting themselves at hospitals. (2) The texture of the conjunctiva of the Egyptians being of a more resistant nature than that of Europeans. (3) The technique used being of a more adroit nature than that in Europe. (4) Greater liability to endogenous infection in Europe than in Egypt. It is impossible to form a definite opinion at the present time on this important matter.

It must be remembered that the cases here considered were all hospital patients, who instantly agreed to whatever operative treatment was proposed by the hospital surgeon, a very different state of affairs to that obtaining in Europe among glaucoma patients.

Cataract Operations.

The operation of election in the 641 extractions of senile cataract performed during 1922 was the combined operation of extraction with iridectomy. In certain cases of complicated cataract a preliminary iridectomy was performed. Loss of vitreous is an exceedingly serious event in the operation and one to be avoided by every means in the power of the operator, as in such a large number of cases detachment of the retina occurs either as an immediate or as a delayed sequela of the operation. The average of vitreous loss for 33 operators of 6·8 per cent. seems to be not excessive as compared with the results published by those surgeons in other countries who go in for what may be called the more fancy operations. It must be remembered that some of our surgeons are very junior, also that complicated operations are more frequent than in England, owing to the effect of trachoma and acute ophthalmias. A selection of the operation which best suits the operator, which can be performed in the minimum time with the minimum disturbance of the tissues, and which is least likely to be followed by loss of vitreous is obviously the best line to take. The six months, June to the end of November, corresponding to the warmer months of the year, are those in which the amount of clinical work is at its maximum.

Acute Ophthalmia.

The importance of applying treatment as soon as an attack of acute ophthalmia appears is, of course, self-evident. Frequently, however, the patient defers coming to the hospital until ulceration of the cornea has already developed. In these cases whatever may be the bacteriological cause of the condition, the local treatment is the same, thorough swabbing of the conjunctiva of the everted upper and lower lids with silver nitrate 2 per cent. in the morning (and again in the evening in all severe cases, taking care, however, not to cause excessive necrosis of the superficial epithelium). Constant washing of the eyes by the patient himself under supervision, with, if possible, occasional irrigation of the conjunctival sac by the surgeon, with ordinary surgical eusol solution is to be used. If, owing to the weather or other conditions, the eusol cannot be utilized at its full strength, potassium permanganoate solution of a strength of 1 in 5,000 should be used. A very small percentage of patients who come under treatment before ulceration develops, suffer any damage to the cornea. The organisms most frequently found were in the following order (in cases in which the cornea was ulcerated) pneumococcus, mixed infection, gonococcus, Morax-Axenfeld bacillus, Koch-Weeks bacillus.

Membranous Conjunctivitis.

Membranous conjunctivitis is not uncommon in Egypt, especially during the warmer months. Up to the present time microscopical examination of the conjunctival discharge with an oil immersion lens has always failed to show the presence of organisms other than the gonococcus, the Koch-Weeks bacillus, the pneumococcus, the staphylococcus, the streptococcus, Morax-Axenfeld or Xerosis bacillus. During August and September of the year 1922, however, a diphtheritic condition being suspected, material was sent up to the Public Health Laboratories in order that cultures might be

made. In a certain number of cases the results were positive and warning having been issued to all hospitals, special precautions were taken to prevent the spread of this dangerous condition. A *résumé* of this subject only can be given here. The organisms in twenty-two cases were reported from the Public Health Laboratories as having been shown after culture to be identical in morphological features with the Klebs-Löffler bacillus. And by exhaustive animal experimentation four of these twenty-two cases were proved to have been actually caused by this organism. It is, of course, clear that time would not allow of more than four cases being subjected to the necessarily prolonged investigation required by modern bacteriologists for the complete proof of the nature of the organism as being actually the Klebs-Löffler bacillus causative of diphtheria. One or two points stand out as certain from recent experience. It is quite impossible on clinical grounds to state whether or not a case of membranous conjunctivitis is due to the diphtheria bacillus or not. Another equally important point is that microscopical examination with an oil immersion objective of a stained film of the conjunctival discharge is without importance as regards an exact diagnosis. In several cases in which animal experimentation fully showed that the condition of infection with the bacillus diphtheria was present, a careful examination of the discharge only showed the presence of an organism resembling the gonococcus, the Koch-Weeks bacillus, &c.

Infectious Diseases.

Typhus and Relapsing.

The reduction in the number of cases of the principal infectious diseases noted as having begun in the year 1920 has been continued in 1922 as regards typhus and relapsing fever. Thus in 1922 only 170 cases of relapsing fever were recorded, as against 1,217 in 1921 and 2,876 in 1920. This is the smallest number recorded during the last ten years.

The diminution in typhus fever has been much more marked. Only 2,484 cases were recorded in 1922, as against 4,476 in 1921. This, too, in the case of this disease is the smallest number recorded during the last ten years.

The diminution in these diseases is very satisfactory. As stated in last year's report, some part of this reduction may be attributed to increase in knowledge among the populace of the part played by the louse in the dissemination of these diseases and to the considerable improvement in the methods of delousing.

Small-pox.

Although the number recorded during 1922 (305 cases) exceeded that which occurred in 1921, yet it is satisfactory to note that this number is far less than the number of cases which occurred in any of the 20 years previous to 1921. This is due to the general vaccination referred to in last year's report, which campaign was begun in 1919 and finished in 1921. Nearly all the cases which occurred in 1922 had escaped vaccination during the general vaccination campaign. 203 cases out of 305 total occurred in Girga Mudiriya and consequently the whole Mudiriya has been revaccinated.

Plague.

The total number of plague cases in 1922 was 487, as compared with 256 in 1921. The number of deaths in 1922 was 228, showing a mortality of 46·8 per cent. The death-rate in 1922, although higher than in 1921, is low when compared with previous years. Of the 487 cases which occurred in 1920, 448 cases were bubonic, 10 pneumonic, and 29 septicæmic. Thus the proportion of pneumonic cases to bubonic was 2·20 per cent. Of the 487 cases 193 cases occurred in the ports, i.e., 71 cases in Alexandria, 54 cases in Port Said, and 58 cases in Suez. The remaining 304 cases occurred in the interior. Of these, 60 occurred in Tanta in a village called Birma.

Malaria.

The amount of malaria in the country was normal. The number of malaria cases notified during the year 1921 was 2,012, and during the year 1922 1,078.

Influenza.

There was no serious outbreak of influenza. The type was mild. The number of cases notified during 1922 was 4,493.

Antirabic Institute.

In 1922, a total of 2,411 cases of bites were reported to the institute. From this number the following deductions should be made: 933 persons not treated at all, the biting animal was found by the Veterinary Service to be non-rabid. 5 persons who ceased to attend for treatment without a satisfactory reason. 121 persons whose treatment was discontinued as being unnecessary, the observation of the animal for a period of ten days or more having shown it not to be rabid. 2 persons whose treatment, although completed, must be considered useless, the animal inflicting the bite having been proved healthy by inoculation of rabbits. The statistics, therefore, comprise 1,350 patients. This figure is an increase of 190 over the number treated in 1921.

Notes on the Animals Inflicting the Bite.

(1) It is to be noted that the number of persons bitten does not correspond to the number of the animals causing the bites reported by the veterinary service, as in several cases one animal caused the injury to more than one person.

(2) As a result of their observation by the veterinary service, 1,050 animals, having bitten 1,054 persons, were found to be non-rabid.

(3) Experimental inoculation of rabbits undertaken at the institute showed, up to the present, that two animals, having bitten two persons, were healthy (some rabbits inoculated are still under observation).

(4) In a certain number of cases, definite diagnosis could not be established, and these cases are considered as suspect. The details are as follows:—

558 animals escaped and could not be found.

70 animals were killed and the carcase destroyed.

175 brains of animals arrived at the institute in a state of decomposition and no investigation was possible.

49 animals remained suspect, the rabbit inoculated being inconclusive.

The total of suspected animals is therefore 852.

(5) Rabies was considered to be proved in the case of 51 animals having bitten 123 persons. The diagnosis was determined:—

By the veterinary inspectors in the case of 9 animals (7 dogs and 2 donkeys) having bitten 17 persons.

By rabbit inoculation in the case of 42 animals (39 dogs, 1 cat, 1 donkey and 1 rat) having bitten 106 persons.

(6) In the case of 15 animals, having bitten 44 persons, positive diagnosis of rabies is presumed by the death of one or more of the patients bitten.

Method of Treatment.

From July 1, 1922, and after the occurrence of a case of death which took place under doubtful circumstances, and which may expose the method of treatment to criticism, the treatment was modified as follows: emulsions are heated for 20 minutes at 56° C. in a bain-marie. This temperature, according to the experiments of Babes, and then carried out in our Antirabic Institute, is sufficient to attenuate the virus of rabies, but not to sterilize it so that it will be harmless when inoculated subcutaneously. The result of treatment during the next year will show if this procedure gives as satisfactory results.

Colonial Medical Reports.—No. 195.—Sierra Leone.

ANNUAL MEDICAL AND SANITARY REPORT FOR THE YEAR 1924.

PUBLIC HEALTH.

General Remarks.

The general health of the European community may on the whole be considered satisfactory. The invaliding rates per 100 residents was 7·92, as compared with 13·72 for the previous year.

Malaria was, as usual, the most common individual cause of sickness. Sixty-one among in-patients and fifty-eight out-patients in a total of 152 and 395 cases, respectively.

There is an increase of 6,938 of total new cases treated, 248 more in-patients and 6,690 more out-patients. This increase does not mean that the amount of sickness was greater, but that an increasing number of people appreciate the benefits of European medicine. An even more satisfactory feature is the large increase (30,091) in the number of subsequent attendances. It is always difficult to persuade patients to continue treatment after the first symptoms have subsided; and that the difficulty is being overcome shows an increasing faith in treatment, the result not of hearsay but of personal experience of the benefits to be obtained.

Sierra Leone was free from any epidemics throughout the year.

Communicable Diseases.

Dysentery.—A total number of 475 cases, showing an increase of 175. These figures need not be taken too seriously, as a very large proportion of the total number is returned from out-station dispensaries where the diagnosis is made by the dispenser on clinical symptoms only.

Tuberculosis.—The number of cases treated shows a slight decrease, but there can be no doubt that this disease is becoming increasingly prevalent. The increase in the number of subacute cases points to the fact that the disease is becoming established here. A departmental committee has been appointed to consider what steps can be taken for the control and treatment of the disease. Meanwhile, in the case of Freetown, the registrar of births and deaths informs the medical officer of health of all deaths returned as due to tuberculosis; the premises are then inspected and disinfected and advice given *re* overcrowding, &c.

Venereal Diseases.—Both gonorrhœa and syphilis show a considerable increase in the number of cases presenting themselves for treatment, but this probably indicates a greater faith in modern treatment rather than an actual increase in the incidence of the disease.

Malaria.—There is a small increase of 457 in the number of cases treated—3,492, against 3,035 for 1923. The deaths from malaria were 12, or a case mortality of 0·34 per cent.

Blackwater Fever.—There were 7 cases during the year with 1 death.

Trypanosomiasis.—2 cases only were reported.

Leprosy.—25 new cases were reported during the year. Of these, only 5 could be persuaded to submit to any treatment, and all these 5 absconded

after only one injection of moogrol or gorli seed oil. One nodular case remaining from 1923 continued to do well on moogrol.

Ankylostomiasis.—This invasion is general throughout the Colony and Protectorate. Each medical officer submits an annual special report on this disease.

Preventive Measures against Insect-borne Diseases.

Malaria.

The following is taken from the report of the medical officer of health, Freetown:—

House-to-House Inspection.—100,656 inspections of houses and compounds were carried out during the year, 353 mosquito breeding places being found. 353 prosecutions followed with 314 convictions. Total fines amounted to £77 10s., an average fine of 4s. 11d. per case.

Mosquito Breeding Places.—The total number of mosquito breeding places discovered and dealt with was 796.

Closing of Wells.—One well, the existence of which was only discovered during 1924, was closed by the Public Works Department.

Cesspools.—Disinfection of cesspools was carried out during the dry season and 11,057 cesspools were oiled during the rains.

Canalization of Streams.—Alligator, Sanders and Nicoll's brooks were regulated and canalized towards the end of the year and all mosquito breeding pools, &c., were obliterated.

Oiling of Pools and Gutters.—79,886 pools and gutters were oiled by inspectors in charge of sections and 31,708 by the oiling gang, which operated for six months of the year. Total 111,594.

Inspection of Trees.—32,440 trees were inspected during the year and 20,495 holes likely to hold water were discovered. 13,372 of these holes were cemented and 7,123 were cut so as to prevent water lodging there. 319 mosquito breeding places were found.

Inspection of Boats and Canoes.—6,547 boats and canoes were inspected for stagnant water and 2,159 were oiled.

Drainage.—Drainage work was carried out by the sanitary engineer and existing drains improved.

Trypanosomiasis.

Two cases were seen; clinically they were typical of the disease, but in neither case was the trypanosome found nor was a post mortem obtained.

(*i*) The case was admitted to the wards from out-patients; the diagnosis was clinical and not confirmed by the laboratory. The relatives gave a history of several months fever and drowsiness. The patient presented a typical picture of late trypanosomiasis, there was evidence that there had been extensive cervical adenitis and a good amount of scarring, the result of native treatment. Extreme lethargy and nervous tremors completed the picture.

(*ii*) Patient admitted to the male infirmary on July 4, sent from Freetown with a provisional diagnosis of trypanosome infection. There were enlarged glands in the neck and he was wont to go off to sleep at all times. The blood examined on several occasions, but no trypanosomes were seen. The glands were not punctured. He had a history of having been in the Congo.

During the year further work was done by prison labour at Cape Sanitary Station, a further extent was cleared and planted with Efwatakala grass. At the end of the year more than half the peninsula was completely cleared, and half this cleared area well planted.

Relapsing Fever.

No case was reported during the year. All medical officers in out-stations had special instructions to be on the look-out for cases, owing to the outbreak in Nigeria, Gold Coast and Fresh territory; special endeavours to find cases in Freetown gave no results.

Preventive Measures against Infectious and Epidemic Diseases.

Cerebro-spinal Meningitis, Influenza.

No cases of cerebro-spinal fever or influenza were reported.

Plague.

No cases were found during the year. 12,708 rats were brought to the department and destroyed; these were paid for at the rate of 1d. per head. A systematic examination of rats for *B. pestis* was commenced at the end of November at the laboratory of the medical department. No infected rats were found.

From March till the end of the year the Gold Coast was infected with plague and, for the last four months of the year, Lagos. Practically all deck-hands of the ships are recruited and discharged in Freetown. This entailed rigid supervision of every homeward bound ship calling here, quarantining all deck-hands and deck-passengers who had been in an infected port within the specified time and disinfection of their belongings. The sanitary departments of the Gold Coast and Nigeria are to be congratulated on the excellent preventive measures adopted and so effectively carried out.

Small-pox, Chicken-pox, Vaccination.

Sierra Leone was unusually free from small-pox during the year. Two suspicious cases were diagnosed as doubtful and treated as small-pox in the Infectious Diseases Hospital. In the Protectorate 10 cases were notified, one at Kumrabai Mamilla (Bambali District), 6 in the Imperri chiefdoms (Gbangbama District) and 3 at Kaiyima (Konno District). Chicken-pox was frequently reported in various parts of the Colony and Protectorate.

Owing to the abolition of specially appointed vaccinators in the Protectorate, the number of vaccinations during the last two years shows an apparent falling off. Vaccination is now being carried out more efficiently and under close supervision by sani-

tary inspectors and dispensers, and every effort is being made to increase the amount done.

Dysentery.

According to the reports from the Connaught Hospital there would appear to be a great apparent reduction, i.e., 42 cases in 1924, as against 138 in the previous year. Practically speaking this disease is now negligible in Freetown.

Tuberculosis.

It is the general opinion that tuberculosis is very noticeably on the increase in the Colony. Towards the end of the year a committee was formed to report on the prevalence, spread, &c., and to suggest means of dealing with same, to report, *inter alia*, on the advisability of rendering it a notifiable disease. Up to the end of the year the report was unfinished.

Anthrax.

There were 4 cases of anthrax in animals discovered during the year, diagnosis being confirmed by bacteriological examination. No human cases were found.

Measles.

Two cases of measles were admitted to the Infectious Diseases Hospital during the year.

Other Diseases.

Diphtheria was not seen during the year. Sporadic cases of whooping-cough were seen, no epidemic was reported.

Port Sanitary Work, Freetown.

The port was in quarantine during the year. All ships arriving from infected places were examined by the medical officer of health and, when necessary, action taken.

Owing to the numerous places infected with plague, &c., the port sanitary work was greatly increased; the crew and deck passengers of all ships coming from a plague-infected port were individually examined. This entailed an amount of extra work on the medical officer of health, who is also port medical officer, and on several occasions his whole day was spent on port work. In Freetown the ships anchor in the river at various distances from the bank, and, although there is no surf condition as is experienced further down the coast, yet when the weather is rough and the current is strong it has taken forty minutes to one hour to get alongside a ship lying far out. Sometimes the only means of getting on board or leaving the ship is by climbing a rope ladder—no pleasant matter during torrential rains, high wind, and with a six-knot current running. The medical officer of health has been known to have been completely ducked in the river, and I have several times seen his clothes ruined with grease, tar and oil. Once I had a request that the department should buy him a new suit. Outside the department it is not realized what an unpleasant, arduous and often dangerous job ship-boarding is here. The provision of a motor-boat for the port medical officer is absolutely essential, unless the question of appointing another officer for this work, other than the medical officer of health, is considered.

Measures taken to Spread the Knowledge of Hygiene and Sanitation.

The usual courses of lectures to sanitary learners in connection with the syllabus laid down in the regulations were given by the medical officer of health. These courses were also taken by male nurses in training at the Connaught Hospital. Sanitary learners also receive instruction in office routine, outdoor sanitary work in all its branches, police-court duties and so on, under the observation of the medical officer of health and superintendent sanitary inspectors.

The death-rate of 25·9 per 1,000 in Freetown in 1924 compares with a rate of 30 per 1,000 in 1923, the actual number of deaths being 1,332 in 1923 and 1,143 in 1924. There was an increase in the number of births registered from 853 in 1923 to 982 in 1924, but in spite of the efforts of the registrar's officer, assisted by the sanitary staff, registration of births must still be regarded as incomplete.

Connaught Hospital and Laboratory Report.

During the year 2,258 specimens were sent for examination.

Nursing Home and Connaught Hospital.

Blood Infection.—644 samples were examined, chiefly from cases of suspected malaria. *Plasmodium falciparum* was found on 173 occasions, *P. vivax* accounted for 12 cases and *P. malariæ* for 9. Malaria was specially prevalent during the months of April, May and June, and during this period only were sexual forms of *P. falciparum* found in films from adult natives. Of the blood microfilariæ, *Filaria bancrofti* was found on 7 and *Filaria loa* on 4 occasions. Chemical, microscopical or spectroscopical examinations were made of 267 specimens of urine. 130 specimens of sputum were examined, in 31 of which *B. tuberculosis* was found. This bears out our clinical observation that tuberculosis is increasing in Freetown. 46 specimens of pus, chiefly from cases of venereal disease, were examined. 3 cases of leprosy were diagnosed from microscopic findings during the year.

Helminthic Infection.—The high percentage of specimens showing infection with ova or larvæ of various helminths is still maintained, the most common parasite being *Ascaris lumbricoides*. Slightly less common are *Ankylostomidæ* followed by *Trichuris trichiura*, *Strongyloides stercoralis* and Tæniidæ. *Oxyuris vermicularis* is very uncommon. 503 specimens of fæces were examined, Many of the cases show infection with more than one parasite, the most common association being ascaris with ankylostoma. 2 cases had infection with 4 different varieties of ova. *Entamœba histolytica*, either encysted or in free forms,

was found on 38 occasions. Of the non-pathogenic amœbæ, *Entamœba coli* is most commonly found followed by *Iodamœba butschlii* and *Endolimax nana*. Of the intestinal flagellates, *Lamblia intestinalis* is found most frequently, in the majority of cases, associated with clinical dysentery.

Miscellaneous.—A daily examination has been made on rats caught in different localities in Freetown. Smears from the spleen and glands are made from each animal and so far no infection from *B. pestis* has been found. Cases of poisoning from impurities present in carbon tetrachloride have been recently reported from various countries. Periodical chemical tests of samples of this drug from the dispensary have been made to detect the presence of carbon bisulphide. Samples so far examined have been free from this impurity and no ill-effects have been seen from the use of this drug in the wards. The usual dose employed is 1 dr. repeated after one day's interval. Several slides from suspected cases of anthrax in cattle were examined. Sections of several tumours were made for purposes of diagnosis.

Notes on a Mosquito Survey at Daru, Sierra Leone.[1]

I.—*Introduction.*

This survey was carried out during the period September 17 to 28, 1924, that is at the end of the rainy season. The maximum temperature recorded during this period was 83° F., and the minimum 69° F.

The investigation was primarily directed to the discovery of mosquito, especially anopheline, breeding places, and secondarily to evolving methods by which the breeding places could be eradicated or controlled. Questions of general sanitation, e.g., water supply, housing, conservancy and refuse disposal, were also gone into as far as was possible in the limited time available, but are omitted from this extract from the original report.

II.—*Description of the Cantonment.*

The cantonment is situated on slightly raised ground on the right bank of the River Moa. There are two sets of officers' quarters with the officers' mess situated between them. One set of the officers' quarters and both the headquarters and A Company lines face the River Moa, the other set is situated higher up above the valley from the hospital to Swamp A. Just above the barracks is the railway bridge over the river, and beyond the bridge at a distance from it of about 200 yards is a creek which forms the outlet into the river of the swamp. Some distance below the barracks is a second creek which forms the outlet into the river of the second swamp. The two swamps A and B arise at a common watershed situated behind the barracks and pass above and below it, skirting it to reach the river. The barracks are therefore almost completely encircled by river and swamp. It will be seen later that certain streams which are feeders of these swamps and of the river arise actually in the barracks grounds.

At the time of this examination, the river Moa had arisen and overflowed its banks in front of the officers' quarters and part of the men's lines; the level reached by the water was stated to be higher than it had been during the previous eight years. The rise in the river level was accompanied by a corresponding rise in the level of the water in both the swamps A and B and in their branches and feeder streams. It was at once evident that if anopheline mosquitoes were breeding at the edges of the river and swamps, the process of flooding must inevitably bring them into much closer proximity to the houses, especially to those occupied by the officers.

III.—*Mosquito Survey.*

(*A*) *Breeding Places. Mosquito Traps.*—27 water traps put down in various sites in the camp, but of these 5 were discarded owing to accidents. 22 remained; of these 22, there were 9, that is 41 per cent., which had mosquitoes breeding in them. Of these 9, 8 contained only culicine larvæ, while 1 contained both culicine and anopheline larvæ; in several cases larvæ belonging to different broods were present in the same trap. While this experiment demonstrated the very general prevalence of mosquitoes around and in the barracks grounds, it proved in the end only of confirmatory value, because while it was in progress the direct discovery of breeding places had already revealed a somewhat disturbing state of affairs.

The Moa River.—The bank of the river was examined from the creek above the railway bridge down to the creek beyond A Company lines. For the sake of clearness in description this stretch may be divided into sections.

Section I extends from the creek above the railway down to the bridge. The bank was several feet high in parts of this section, but in other parts it sloped gradually down to the water; in all this section it was covered with thin bush or coarse grass. Along the edge anopheline larvæ and pupæ were found in fair numbers.

Section II extends from the railway bridge to the end of the area occupied by the officers' quarters. Along this section the bank was grass covered and sloped gently down to the water's edges. In the margin of the river throughout this section anopheline larvæ and pupæ were numerous.

Section III extends along the front of headquarters lines. In this area the river bank is high, being 8 ft. to 12 ft. above the water; the water runs along bare soil with no shelter for mosquito breeding purposes. No anopheline larvæ or pupæ were found here.

[1] These notes form part of a report presented to the Government of Sierra Leone.

Colonial Medical Reports.—No. 195.—Sierra Leone
(continued).

Section IV extends along the front of A company lines. This area has banks which slope gradually down to the water's edge; in this respect it resembles closely Section II. No anopheline larvæ or pupæ were found here. The reason for this appears to be that in this section opposite A company lines, the bank had been completely denuded of grass and weeds. This simple alteration in the character of the bank is apparently responsible for the important difference in anopheline breeding. Thus the river's edge in Section II yielded on September 17 over 150 anopheline larvæ and pupæ, while the river's edge in Section IV on the same date yielded none.

Section V extends from the far end of A company lines at the end of the barracks ground to the creek below. The bank here was bushy and flat, and larvæ and pupæ of anophelines were present in fair numbers.

If we turn attention more particularly to the three sections which lie immediately opposite the barracks we note several points of interest. Section II, for example, grass-covered and with a gentle slope affords excellent breeding shelter for anophelines when the water in the river is low; as the water rises the gentle slope of the ground permits the water to encroach nearer to the officers' quarters, and as it rises it brings with it the larvæ and pupæ already bred in it; in addition, it forms grassy pools in which both anophelines and culicines lay their eggs. Section III has steep banks and when the water is low it affords little shelter for anopheline breeding. Even when the water rises it is still confined by the bank and no breeding places are formed.

A factor which has a secondary influence in Sections II and III arises out of the configuration of the river at these points. The bank of Section II is concave towards the river, while that of Section III is convex. The result is that the water which spreads out and is sluggish in flow at the edge of Section II is restricted and more rapid in flow along the edge of Section III.

Section VI, of which the bank is sloping but bare, affords no shelter for anopheline breeding. Hence when the water rises here it does not bring with it larvæ and pupæ. Furthermore, as the whole of the bank even above high water mark is bare, no grassy pools are left in which anophelines and culicines can breed when the river recedes.

The detailed study of these three sections, therefore, reveals important factors bearing on the bionomics of the river bank anophelines. It will be observed that advantage can be taken of the information so obtained in such a way as to eliminate anopheline breeding places in those sections where they are at present found. The remedial measures which may be used to accomplish this most economically will be discussed later.

There are several additional facts which must be taken into account while dealing with the river.

(*a*) *Tributary Streams.*—Several small irregular water courses, partly from springs, partly from surface drainage, run down to the river from higher ground upon which the barracks are situated. One of these deserves special attention. It is that stream which lies between headquarters lines and A company lines. This stream has clear water derived from a spring on the high ground; it has in it and at its edges a considerable quantity of grass and weed. As it passes down it spreads out on approaching the river, and in this part it is heavily fringed with grass. In the lower part of this stream anopheline larvæ were found.

(*b*) *Fallen Trees.*—Along the edge of the river several trees have fallen into the water; many of these have large holes in them which the river water fills when the river is high. Owing to the excessive height of the water at the time of this visit the holes were flooded out by the river. It is more than probable, however, that as the river recedes the holes which retain water, many of them of large size, will act as breeding places for mosquitoes.

(*c*) *Rocks.*—As the river falls a reef of rocks is exposed to the centre of the river, and rocky pools are left in large numbers. It is almost certain that these pools will breed mosquitoes.

Swamp A.—This swamp was followed from the mouth of the creek by which it enters the river above the railway bridge to its source behind the barracks at the back of Boma town; anopheline and culicine larvæ and pupæ were found in large numbers along its whole length. The character of the swamp changes as it passes up towards its commencement. Where it lies on the far side of the railway it is deep and has strong bush growing along its margins. Soon after crossing under the railway it becomes shallower, and in its upper part it is covered with a matting of coarse grass. It was possible at this point to walk over it, but each step left a pool of water from which larvæ and pupæ of anophelines were almost invariably recovered.

The Hospital Drain.—In passing upwards along the Swamp A from the creek it was observed that a drain leading from the hospital joined it by passing under the railway. It was found that the ground just inside the railway on the way to the hospital was marshy, and that in this marshy ground anophelines as well as culicines were breeding.

The drain from the hospital on the high ground comes down a steep hill, and then flattens out and passes with a gradual slope in the railway embankment, under which it passes to join Swamp A beyond the railway. The condition of the drain at the time of examination was as follows:—

" Owing to the rise of the swamp water the culvert under the railway was full to the top. The water of the drain had overflowed the edges and a large triangular area of ground was rendered swampy. As a result of the rise of the swamp water, therefore, the drain was no longer able to carry away the water from the hospital area. On the contrary, water from the swamp had passed up

along the drain to a point midway between the railway and the hospital. In the water thus carried up anopheline larvæ and pupæ were present; these came from the marshy triangular area at the railway and probably also from the swamp beyond the railway. This drain then, as now laid, is not effective in carrying away water at times when the river is high; not only so, but it acts as an easy route by which anophelines may be brought right into the heart of the barracks grounds, to a position where they could not exist if this drain were not there. The danger of this anopheline breeding place and the drain can best be emphasized by pointing out that several officers' houses are within 100 yards on one side, while the hosptial and British non-commissioned officers' houses are at a similar distance on the opposite side."

Swamp B.—This was followed from the creek by which it opened into the river upwards to its source beyond the rifle range. Anopheline larvæ and pupæ were found along its margin, but by no means in such large numbers as was the case in Swamp A. At one point this swamp has close relationship to the barracks. Outside the barracks grounds is a feeder stream which runs to Swamp B. This stream is very difficult to approach owing to the dense growth of bush and grass which covers it. Yet in it, within 150 yards from the nearest house in the barracks, numerous anopheline larvæ and pupæ were found. This is the nearest point to which the waters of Swamp B approach the barracks.

Mosquito Breeding in the Barracks Grounds: (*a*) *Artificial Water Containers.*—The tanks which receive roof water were examined for larvæ and pupæ. The roof gutters of the hospital sagged in places and afforded a lodgment for water; this was also searched; in neither case were breeding places found. A wooden mortar standing beside the river at the women's washing place contained a little water; this was seething with larvæ and pupæ of culicines. A pail of water standing at the place where the latrine buckets are emptied contained culicine larvæ and pupæ. Apart from these two isolated and remote instances, no artificial containers were found breeding mosquitoes. The whole barracks grounds were commendably free from derelict tins, bottles and other objects capable of harbouring mosquito larvæ.

(*b*) *Wells.*—There is only one well situated in the mess grounds. This is about thirty feet deep and is in rock; it is disused; it contained only a few inches of water; in this culicine larvæ were found.

(*c*) *Trees and Shrubs.*—The large number of trees and shrubs in the ground at Daru is quite a feature of the landscape; especially in the neighbourhood of the officers' quarters and the officers' mess. While some of the trees are of economic value, by far the majority are purely of æsthetic value. Although, as will be shown below, many of these form breeding places for culicine mosquitoes, it would be very unwise to adopt any panic policy with regard to them; the value of good trees for shade purposes is very considerable, and there is no necessity to take steps which may later be regretted. If the regular routine inspection and treatment which is recommended later is carried out, it should not be necessary to sacrifice a single useful or ornamental tree.

The investigation of breeding places in trees and shrubs was carried out in a systematic manner; it proved no easy task, but great assistance was obtained from natives employed. These were first of all trained in their duties; each tree and shrub was carefully examined for holes which might contain water; if such a cavity was found, a piece of native string was tied to the shrub or tree. Any which actually contained water were marked by a second string. In two days four men had marked in this way all trees and shrubs found capable of, or actually containing water. When they reported their task finished a rapid survey was made of all unmarked trees and shrubs; in surprisingly few cases had possible breeding places been overlooked. Attention was next turned to the marked ones, and each water collection was in turn carefully examined for larvæ or pupæ of mosquitoes. In this way a large number of breeding places was discovered and each was dealt with or else marked in a permanent manner in order that it might be radically treated.

It should be observed here that no instance of anopheline breeding in such places was found. This corresponds with the results obtained by Bacot in Freetown in 1915, and also with those at present being obtained by the sanitary department there in their survey of trees. It is true that Bacot found one breeding place of *Anopheles costalis* in connection with a tree. This was a pool formed on the buttress root of a silk cotton tree at ground level; it was simply a pool of water lying on the unbroken bark; it would appear to be analogous to a rock pool and not an instance of a true tree-hole breeding place.

In the ground of the officers' mess alone forty-two collections of water were found in holes of trees, in tree forks, in leaf axils and in shrubs. Of the forty-two collections of water thirty-three contained larvæ and pupæ of mosquitoes. Nearly two-thirds of the breeding places were in the clumps of bamboo near the tennis court. Many of these had been cut in such a way as to leave a little tube containing water above the point. Most of these breeding places were dealt with at once while making the survey.

In the grounds generally breeding places were found in all clumps of banana examined, either in rotten stems or in the healthy trees in the wet clefts between the petioles. Pineapple plants provided many breeding places. Large trees were found to breed in collections of water in the forks, and in rot holes where branches had broken off or been cut. Much more frequently, however, breeding places were found near the ground level, on exposed roots.

(*B*) *Adult Anophelines.*—The preliminary survey of the river and swamp waters had shown that anopheline breeding was going on all round the

cantonment and in feeder streams arising in the barracks grounds. The survey of trees and shrubs had shown that while culicines were breeding in such sites in the barracks, anophelines were not breeding there. Search was next made for adult anophelines. (*i*) *Officers' Quarters*: Examination of the officers' quarters showed that *Anopheline costalis* were entering the barracks to feed, they were present in small numbers in the quarters. *Anopheline nili*, although breeding on the river margin close to the quarters, was not found in them. (*ii*) *Native Houses*: Adjacent to the first house of the officers' quarters is a house occupied by the family of a native servant. On several days in succession adults were searched for here, and were always captured in considerable numbers. Over 100 fed females of *A. costalis* were caught altogether here and also one fed female of *A. nili*. It is worthy of remark that this was the solitary occasion on which *A. nili* was captured in a house. That this mosquito is prepared to feed on huuman beings was proved by the fact that on one occasion three out of a number of bred specimens fed well, inflicting a bite which was not by any means painless; that is to say that the bite would have attracted attention. It is not without interest, that whereas this native house daily contained numerous fed anophelines, the officers' house immediately adjacent to it, and the other officers' quarters remained comparatively free of anophelines; this appears to be the case even when due allowance is made for the size and height of the houses.

To sum up, the evidence from this survey of houses supported the belief that the anophelines which had made their way into the officers' houses had come from Swamp A. Further, the evidence pointed to the fact that in their progress from the swamp in search of blood the female anophelines stopped at the first house they encountered and stayed there as a rule; there was, however, some tendency to overflow into the barracks quarters. The fact that the few native houses intervening between the swamps and the cantonment acted thus as a more or less efficient screen for the camp is important. Any feeling of security derived from this consideration must, however, be balanced against certain dangers which such a screen may give rise to, namely, the dangers of the overflow mosquitoes carrying infection with them from the infected natives.

(*C*) *Identification of Mosquitoes.*—With the exception of numerous adult female *A. costalis* and one female *A. nili* captured, all the specimens identified were reared from pupæ or larvæ.

The identifications were made for me by Miss A. M. Evans, Liverpool School of Tropical Medicine, The Daru collection consisted of twenty-two species and included one new species and one new variety and several species which have not hitherto been recorded from Sierra Leone, i.e., *Anopheles costalis* (Loew), *A. mauritianus* (Grand), *A. umbrosus* (Theo.), *A. nili* (Theo.), *Culex* (*Culiciomyia*) *nebulosus* (Theo.), *Aëdes* (*Stegomyia*) *africanus* (Theo.), *Aëd.* (*Finlaya*) *longipalpis* (Grunb.), *Eretmopodites chrysogaster* (Graham), *Toxorhynchites brevipalpis* (Theo.), *Aëd.* (*Stegomyia*) *blacklocki* (n. sp.), *Aëd.* (*Aëdimorphus*) *tarsalis* (Newst.), *Aëd.* (*Stegomyia*) *simpsoni* (Theo.), *C. Decens* var. *invidiosus* (Theo.), *Lutzia tigripes* var. *fusca* (Theo.), *Aëd.* (*Aëdimorphus*) *domesticus* (Theo.), *Aëd.* (*Stegomyia*) *apicoargenteus* (Theo.), *C. annulioris* (Theo.), *Uranotænia nigripes* (Theo.), *Uranotænia fusca* (Theo.), *Aëd.* (*Stegomyia*) *argenteus* (Poiret), *Aëd.* (*Aëdimorphus*) *comminsi* var. *daruensis* (n. var.), *Mimomyia hispida* (Theo.).

Reviewing these mosquitoes, the commonest anopheline found was *A. costalis*, which was breeding in both Swamps A and B right down to their entrance to the river, in the hospital drain and in the stream between headquarters line and A company lines. *A. nili* was confined to the margin of the river. These two anophelines were the only ones captured in houses, and in the case of *A. nili* only one specimen was so obtained. *A. mauritianus* was found in Swamp B, while *A. umbrosus* was found in the upper portion of Swamp A.

It is worthy of note that among the large number of mosquitoes called *Aëd.* (*Stegomyia*) *argenteus*, the proved carrier of yellow fever was found only in one breeding place, that is, in the latrine bucket containing water. This rarity is probably due chiefly to the adequate measures adopted in the cantonment for the prevention of tins, bottles and other artificial receptacles acting as breeding places. But even so the absence of *Aëd. argenteus* from tree and plant breeding places is remarkable; such breeding places harbour this species not infrequently in the neighbourhood of Freetown. It was observed that the larvæ of megarhinines were usually found alone in small collections of water in trees and plants and their predaceous habits were also observed in breeding-out experiments. It is possible that part of the scarcity of *Aëd. argenteus* at Daru may be connected with the presence of such predaceous larvæ.

IV.—Measures for Reducing Mosquito Breeding.

The steps taken to deal with the breeding places of mosquitoes must be considered largely from the point of view of cost. It would doubtless be possible, if expense were no object, to deal in a radical manner with the breeding places by large schemes of swamp drainage and filling. But such schemes, however desirable, are quite out of the question at Daru at present. Instead, therefore, of suggesting large and comprehensive schemes, the following measures will in a reasonable time and at moderate expenditure greatly diminish the risk of acquiring mosquito-borne diseases in the cantonment.

The first recommendation is that advantage should be taken of the assistance of the native troops in rendering the barracks and its environments more healthy. One native soldier should be detailed each week to act as a mosquito hunter. His whole duty during the week should be to discover breeding

places and, having marked them down, to report them. On his reporting a breeding place, action with regard to it should at once be taken. At the end of each week the man who is to be on duty for the succeeding week should spend two days with him in order to learn his duties.

The results of this procedure will be twofold; firstly, all breeding places will almost infallibly be discovered and dealt with, which is in itself a matter of no small importance; secondly, the knowledge of how to look for, discover and deal with mosquito breeding places will extend steadily among the troops. Each individual will become imbued with ideas which will render him an extremely useful ally in the campaign against insect-borne diseases. The more clearly native troops in tropical countries grasp the essential elements of hygiene, the more efficient they will become as a fighting force, and nowhere is the truth of this statement more evident than in warfare in the African bush.

This educational policy should be the basis of all further action here! It is not a policy which could be carried out successfully in any casual community, but the community of Daru is not a casual one but a highly specialized one. In the circumstances there, there is no hesitation in recommending it as a practical policy which, conscientiously carried out, will produce good results. Its application will now be considered in conjunction with the other recommendations.

(*a*) Minor Operations.—(*i*) Starting from the creek above the railway bridge the edge of the river should be denuded of grass and weed; this process should be carried out along the whole of the front of the barracks where it has not already been done. The side streams leading to the river from the high ground within this limit should be drained and cleared of grass and weed. All trees which have fallen into the river should be dealt with if they are in a position to afford lodgment of water. In case of a rise in the river level, any pools which form on the banks will be examined and reported on by the man on duty. In the dry season there is the additional problem of rock pools on the reef in the river bed. Owing to the high level of the river during my visit it is not possible for me to give in detail measures necessary to eliminate these; a statement is given based on experience of what appears to be similar conditions elsewhere. Wherever the rock pool has a sufficiently thin wall it should be drained permanently by breaking through the wall with a jumper-chisel and sledge hammer. Where the wall of the pool is too solid for such a treatment the pool should be emptied quite dry by syphonage or baling. Failing this resort may be had to filling in with concrete or to the use of oil or chemical treatment of the breeding places.

(*ii*) *Swamp A.*—The first step to be undertaken in the treatment of this swamp is the cutting of the bush along its margin from where the creek enters the river to the point where the stream passes under the railway near the clerk's house. Along this stretch the establishment of farms and gardens would keep the bush cleared from the railway line up to the edge of the swamp. A path or, if necessary, a series of paths should be kept parallel to the edge of the swamp so that it may be readily accessible to the soldier whose duty it is to inspect it for breeding places; these paths should be opened and kept open by each farmer on his particular ground. The edge of the swamp should be kept clean of grass and weeds; each farmer being responsible for that portion opposite his own farm.

(*iii*) *Swamp B.*—Most parts of this swamp are more remote from the barracks than is Swamp A. At one point opposite the parade ground there is a stream in which anophelines breed; it is recommended that a good path be made from the parade ground down to and along this stream and that it should be continued to where the stream enters the swamp. The stream should be cleared of bush, grass and weed, and can then be properly and regularly examined by the soldier on duty. Along that portion of the swamp itself which lies opposite to the present and proposed new lines, the bush should be cleared and farms established on a similar basis to those along the edge of Swamp A.

(*iv*) *Trees, Stumps and Shrubs.*—On the report of the discovery of a potential or actual breeding place in these sites, appropriate action should at once be taken to deal with them. The action will depend on the value of the tree or shrub. In case of stumps and trees of no economic, æsthetic or shade value, removal by felling and digging and blasting is the proper method, the ground being filled in and smoothed afterwards. Where for any reason it is desired to retain the tree or shrub, an outlet for all the water it contains should be cut and the cut surface tarred. Filling in holes with earth or concrete is not recommended except as a last resort in the case of trees of special value which cannot be treated effectively by cutting a channel for the water, since spaces develop later, as the rot hole becomes larger, and breeding goes on between the filling and the tree hole walls.

(*b*) Major Operations.—(*i*) *The Hospital Drain Area.*—As a temporary measure the wet triangular area inside the railway may be trenched so as to collect the water within definite limits. The water in the trenches and in the drain can then be treated with oil, but the permanent obliteration of this marshy area is necessary at the earliest possible time. This can be accomplished by filling in a triangle with its base on the railway and its apex extending to the foot of the slope down which the first portion of the hospital drain runs. As we saw, the present level of the drain to the railway is too low and the water becomes dammed back in it. The drain will therefore require to be relaid at such a level and with such a slope as will allow the water carried by it to pass under the railway and have a fall into the swamp beyond the embankment. In carrying out this operation all material for filling it should be collected and the filling carried out from without inwards, leaving the drain itself to be dealt with as the last of the operation.

Colonial Medical Reports.—No. 195.—Sierra Leone *(continued).*

The proper level to which the ground must be raised will have to be determined by a skilled engineer. In the filling in of this area the railway department could render valuable assistance by surveying the ground and by supplying material for filling. The work could best be carried out in the dry season, but the contingency of exceptional high water in the swamp, as, for example, this year, should be provided for fully in deciding the height of filling required. The only essential points are that the marshy area should be eliminated, that the drain should have a good slope, and that it should have a definite fall into the swamp, even when the water in the swamp stands at an exceptionally high level.

(*ii*) *Permanent Improvement of Swamp A.*—The above operation having been completed, it is advisable to adopt a definite policy with regard to Swamp A. The policy which appears to hold out the best prospects of success is to make a steady and progressive encroachment on the swamp from the railway outwards. By the time this stage is reached the progress of clearing should have so far advanced as to make it possible to define the best limiting line along which filling can be done, so as to leave a straight edge to the reclaimed land beyond which the water of the swamp can be constantly kept. It is here, above all, that the greatest assistance can be given by the railway department. In fact, it does not appear probable that much can be done in this direction without the active co-operation of that department; with this co-operation much could be done. The method of co-operation suggested is that the engineer should determine the best line to leave for the swamp water, and that a siding should be made in which trucks of earth, ashes, stones and other waste material provided by the railway department could stand while their contents are being discharged. The labour required for unloading, transporting the material, and filling in should be provided by the military authorities.

In the case of Daru, if the scheme of filling in Swamp A is adopted, a very useful way of disposal of the majority of the camp refuse would be to utilize it for filling in this swamp. There is an incinerator of small size which can be used for kitchen refuse. The remainder of the camp refuse should be taken to the margin of Swamp A and treated there. The treatment will consist of separating all combustible material and burning it. The incombustible material can be disposed of as follows: The material supplied by the railway having been filled in along a section of the edge of the swamp sufficiently high to raise it above water level, the refuse is laid on in a layer of about two feet thick. This is then covered with a layer of a foot or so of soil and pressed down firmly. In this way a waste product is turned to good account in the sanitation of the cantonment. A small amount of kerosene sprinkled on the refuse before burial would help to prevent fly breeding and by oozing gradually into the swamp act as a useful anti-mosquito agent. The subsidence in the trenched area which will gradually occur can be rectified later by the deposit on the surface of soil from the filling in material supplied by the railway.

Colonial Medical Reports.—No. 196.—Nyasaland Protectorate.

NUAL MEDICAL AND SANITARY REPORT FOR THE YEAR ENDING DECEMBER 31, 1925.

General Diseases.

Beriberi.—Three cases were reported this year, two from Fort Johnston and one from the Central Prison. There were not any reported during the previous year.

Pellagra.—Sixty-three cases were treated with one death, as compared with 137 in the previous year. Of the 63 cases, 43 were reported from the Central Prison and 12 from the lunatic asylum. The cases are being treated with 2 gr. of thyroid extract daily with good results.

Communicable Diseases.

(A) *Insect-borne Diseases.*

Malaria.—During 1925, 3,303 cases were reported with 5 deaths. Of these cases, 2,071 were reported from the rural dispensaries by native dispensers, who have no microscopes. Last year 3,461 cases were reported with one death.

Of the cases in 1925, Europeans numbered 113 (two deaths), as against 76 (one death) in 1924 and 126 (no death) in 1923. Quinine powder in packets of three 5-gr. doses is sold at all post offices for 1d. a packet; 1,025 packets were sold during 1925. Bottles of 100 5-gr. tablets of quinine bihydrochloride are also on sale to the public at all post offices and 1,561 bottles were sold during the year.

Blackwater Fever.—Four cases of blackwater fever were notified with 3 deaths. One of these cases was in an Asiatic and the other 3 in Europeans. The returns for the previous four years were 5, 14, 14 and 11.

Tick Fever.—During the year 128 cases were reported, of which 4 were Europeans: 82 were reported in 1924, 71 in 1923 and 47 in 1922. Most of the cases occur in stations in the northern and central provinces. Fort Johnston and Zomba reported 29 and 32, respectively. Most of the Zomba cases, however, are infected up country; very often

people visit a district where the disease is prevalent, and on their return to Zomba they come to the hospital for treatment.

Trypanosomiasis.—Two cases of sleeping sickness were reported in Africans; both of them died. Both cases were admitted to hospital in the final stage and succumbed shortly after admission.

(B) *Infectious Diseases.*

Small-pox.—One case of small-pox was reported from Mzimba. It is not known how the man became infected.

Chicken-pox.—During 1925, 17 cases (1 European) were reported, as against 70 in 1924

Cerebrospinal Fever.—Five cases were reported, of which 2 died.

Enteric Fever.—Six cases of the enteric group of diseases were treated, of which 1 was a European with typhoid, 2 were natives with paratyphoid, and 3 were undefined cases in natives reported by native dispensers. In 1924 there were 11 cases.

Influenza.—A mild type of influenza occurred which spread over practically the whole country. There were not any deaths reported amongst the 495 cases, of which 15 were Europeans. In 1924 there were 753 cases (17 Europeans) with 1 death.

Leprosy.—During the year 29 cases were treated as compared with 28 during 1924. In addition 14 cases were seen at the rural dispensaries. Moogrol is used for treatment. With a few exceptions, however, the treatment of the cases is not very satisfactory, as the patients do not feel inclined to persevere with the treatment for the requisite length of time. It so often happens that a patient lives many miles from a hospital and will not come in weekly for the injection, nor can he stay in the hospital for the length of time necessary. In some districts much good work could be done if a medical officer could be appointed to devote all his time to leprosy in the district, so that in addition to managing a special hospital he could travel over the district and hold weekly clinics at suitable centres. A single medical officer in a district can only treat cases that come to the hospital; he is not in a position to hold regular clinics in several places. Except in a very few cases the native dispensers are not sufficiently trained to treat cases of leprosy.

A census of lepers was taken in one district, and a plan was proposed for starting a special leper hospital; but funds are not sufficient to carry it out.

Plague.—There were not any cases reported during the year.

Tuberculosis.—Seventy-two cases with 10 deaths occurred, as compared with 45 (9 deaths) in 1924. Of these cases, 27 were reported from Zomba.

Venereal Diseases.—As compared with 183 last year and 72 in 1923, 263 cases of gonorrhœa were treated; of these, 157 were treated at the rural dispensaries.

There were 528 cases of syphilis, as against 576 in 1924; 201 were treated at the rural dispensaries and would not receive such thorough treatment as those at the hospitals, who are treated with novarsenobillon or with injections of bismuth.

Yaws.—The number of cases treated this year was only 760, as compared with 1,776 in 1924. The falling off of cases has occurred in the rural dispensaries, which only treated 307 cases, as against 1,137 in 1924. There were, however, some 900 treated by a mission on the lake shore, under the direction of the medical officer, which are not recorded in the returns.

At the hospitals the large majority of cases were treated with injections of sodium bismuth tartrate with excellent results. In some cases medical officers found that the injection caused a considerable amount of pain, and now a more concentrated solution of the drug is being tried in the hope that it may be less painful.

Helminthic Diseases.—The main helminthic infections in this country are ankylostomes and schistosomes. Infections by ascaris and tænia are also common.

Ankylostomiasis.—Microscopic examinations of the fæces of groups of natives have been made at various times and in various places in order to ascertain approximately to what extent hookworm exists. In some groups at Zomba it was found that over 90 per cent. were infected, whilst at Mlanje a group examined recently revealed an infection of only 28 per cent.

In the ordinary way the infection appears to have little effect on the health of the individual. Under certain conditions, perhaps an unusually heavy infection of ankylostomes, or perhaps semi-starvation, the usual symptoms of ankylostomiasis appear, and then the patient may present himself for treatment. It is thought that the inability to carry out sustained labour is due partly to ankylostome infection and partly to deficient or unsuitable diet.

During 1925, 481 such patients were treated. For treatment carbon tetrachloride is generally used, and this is issued free to employers of labour and all medical men.

The proportion of *americanum* to *duodenale* has not yet been ascertained, but from occasional investigations made it would appear that *americanum* is uncommon and that the infections are mostly *A. duodenale*.

Schistosomiasis.—Two hundred and ninety cases of *S. hæmatobium* and 77 of *S. mansoni* were reported during the year. In addition to these the rural dispensaries reported 38 cases of hæmaturia, of which there is little doubt that a number were due to *S. hæmatobium*. These cases are very common on the lake shore.

Vital Statistics.

General Native Population.

Vital Statistics of the general native population are not available. The population is estimated to be 1,205,801.

General European Population.

During the year 548 cases were treated amongst the general European population by Government medical officers. The numbers treated by medical

officers attached to the missions are not known. There were 6 deaths amongst the 548 cases.

The total number of European deaths recorded by the Registrar-General was 19. The number of births was 48, as compared with 42 in 1924.

European Officials.

During the year there were 95 cases treated amongst officials; of these cases 69 necessitated the officials being off duty. One official died, whilst on leave, from complications following an appendix abscess.

The chief disabilities were: malaria, 25 cases; infections of the upper air passages, 15 cases; minor injuries, 10 cases; diarrhœa, 3 cases.

HYGIENE AND SANITATION.

The absence of the sanitation officer on leave in England makes the compilation of a report upon hygiene and sanitation in the Protectorate a matter of difficulty, and reliance for data has had perforce to rest mainly upon the annual reports sent in by the various medical officers scattered throughout the country. Since only a limited area of the Protectorate is covered by the activities of medical officers and sub-assistant surgeons by reason of the small number of staff, this report must be regarded as somewhat inadequate, although, in the main, it can be taken as reflecting the general state of sanitation in the Protectorate.

(A) GENERAL REVIEW OF THE WORK DONE AND PROGRESS MADE.

(1) *Preventive Measures.*

Mosquito and Insect-borne Diseases.—Preventive measures for the eradication of malaria have been as heretofore of a very limited and temporary character. The sanitary gangs at work in the various townships and on Government stations have done as much as has been possible to keep clear such places as breed and harbour mosquitoes. Sanitary work of a temporary and makeshift character is always unsatisfactory, and since it entails a constantly recurring expenditure of funds is, in the long run, more expensive than works of a permanent nature, and it is unfortunate that the financial state of the country prohibits the carrying out of such works as would make the elimination of malaria a possibility in the more populous parts of the Protectorate. In spite of many difficulties the gangs have been able to effect some slight improvement on the whole. The notable exception to this is seen on such stations as are near the lake or rivers. To attempt anything of even a temporary nature would mean a very considerable increase in the amount allocated to sanitary works.

Trypanosomiasis.—For scientific work done on this problem see the report submitted by Dr. W. A. Lamborn, medical entomologist. No case of sleeping sickness has been reported. The results of the proposed scheme to create barriers to the advance of the tsetse fly into hitherto uninfested areas will be awaited with great interest. The present threatened invasion of highly populous districts can only be viewed with grave uneasiness in view of a possible sudden outbreak of human trypanosomiasis. Beyond a very limited survey made in 1922, at the time of a reported outbreak of the disease when some villages were moved, lack of funds has prevented the continuance of the work done in 1913 with regard to the extent of the disease amongst the natives in Nyasaland.

Epidemics.—During the year the country has been singularly free from outbreaks of infectious diseases. There was an outbreak of measles in the Lilongwe district during the heavy rains; the mortality rate 11·4 per cent. (2,067 cases) was high but not higher than was to be expected in a zymotic disease breaking out during the rainy season, when the housing and mode of living of the natives are taken into consideration.

Efforts to prevent the spread of infectious diseases have consisted merely in the isolation at native hospitals of such cases as have sought relief. Since only a very limited number of natives avail themselves of medical assistance when seriously ill the liability to the outbreak of serious epidemics is constantly present. As regards prevention of the spread of small-pox, the task of vaccinating the natives has been carried out as in former years. The returns are as follows: Number vaccinated, 80,699; successful, 26,973; modified, 22,517; failed, 28,370; not seen, 2,839.

As at present carried out this work can only be regarded as most unsatisfactory. Any medical officer who takes the trouble to go through his district and check the returns submitted by native vaccinators will not go far before he realizes that without supervision the work will not be properly carried out. So much so is this the case that the figures given each year rather tend to give one reading them a sense of false security as regards the protection afforded the natives against small-pox. The amount of money devoted to vaccination is inadequate considering the size of the native population.

Helminthic Diseases.—Efforts to prevent the spread of these diseases can be regarded as fairly successful in the military and police camps. Amongst the general native population, where pit or other latrines have been provided, any benefit that may be expected to accrue from the provision of such facilities is largely nullified by the fact that the women decline to use them and retire to the nearest patch of scrub. This, to a certain extent, holds good with both sexes during the hours of darkness. Even in the townships and on the stations and plantations where proper sanitary provision is made for the natives, the conditions are very bad, whilst in the villages the prevalence of flies in myriads tells its own tale.

(2) *General Measures of Sanitation.*

Night soil and refuse are disposed of by burial, except in Port Herald, where an incinerator is in use. They are buried in pits or trenches, generally in the compounds, but outside if ground is available. In Blantyre they are carted outside the

township and buried. In spite of frequent inspections by the sanitary staff these pits are generally in a foul state. Occasionally one finds a householder in whom the sanitary conscience is developed, but such are the exception rather than the rule, in spite of frequent warnings regarding the risks they run from having insanitary compounds. The very rocky nature of the ground in most parts of Zomba makes the digging of suitable pits well-nigh impossible, and this fact, coupled with the carelessness of householders and their domestics, makes the state of many of the compounds truly deplorable.

Storm-water drainage is effected by means of earth drains. In the township these are being gradually replaced by brick ones.

For the supply of water, for drinking and domestic purposes, reliance is made on springs, streams and wells where lake or river water is not available. Where stream and river is used such is very liable to pollution by natives, since the banks of streams and rivers are naturally favourable sites for their villages. The onset of the rain marks the commencement of outbreaks of enteritis, and there is no reason to assume that these are due entirely to the concomitant increase in the number of flies present in the villages. Well water is often of doubtful purity and seldom are the wells rendered mosquito-proof. In Blantyre rain-water tanks are in use.

In and around all the townships and stations the clearance of grass and undergrowth is carried out as regularly as the supply of labour permits. During the rainy season the want of sufficient funds to permit the employment of enough labour for this work renders it imperfect.

Sanitary inspections are carried out regularly where medical officers and sub-assistant surgeons are stationed. In the townships native sanitary inspectors are employed. Their usefulness is limited to reporting to the medical officer such conditions as appeal to them as being insanitary.

(3) *School Hygiene.*

Except for two small schools for European children all the schools are run by missionary societies. They are kept in a satisfactory state. These schools naturally afford excellent opportunity for instilling into the minds of the young natives ideas regarding personal hygiene as well as sanitation. How far this opportunity is taken advantage of is not known.

(4) *Labour Conditions.*

Industrial conditions in general cannot be said to be very satisfactory from either a medical or economic point of view. Only a comparatively small proportion of the native population have become industrialized in the sense that they are regularly employed throughout the year, and, until we see some serious effort made to improve their conditions whilst employed, mainly as regards health, housing and feeding, there is no reason to expect that proportion to be greatly increased. Should we see an increased desire on the part of the natives to embark upon the production of economic crops suitable for export, it is likely that we shall see a marked decrease in the numbers seeking either skilled or unskilled labour.

Skilled labour is recruited from Government or private workshops and the mission stations. The conditions of those engaged in clerical work are satisfactory. Such, however, cannot be said of those employed at trades requiring any degree of hard manual labour.

One constantly hears complaints regarding the indolence of labourers and their incapacity for any sustained muscular effort. One wonders how much of this is due to the natural laziness of the native and how much to the fact that his dietary is of such a nature as to preclude the possibility of greater muscular output. The dietary of the manual worker differs very little from that of the native sitting in idleness in his village, and that is not suitable for a man engaged in hard work.

Casual labour engaged in Government works is recruited mainly from volunteers with a small percentage of hut-tax defaulters to make up the balance. Labour for factories and plantations is recruited from whatever part of the Protectorate the men can be induced to take up work. The average casual labourer only works for from three to six months of the year, according to his financial needs. During the rest of the year he is building or repairing his huts, preparing new ground for his crops or sitting in idleness at home.

Domestic servants and natives in Government and factory employment are fairly well housed. Such is not the case with regard to the general run of workers, and particularly with regard to the natives employed on plantations. These are generally housed in ramshackle grass and pole huts which are often burned or fall down, and, from the nature of their construction, are insanitary. The general conception seems to be that, since the native lives in such a dwelling in his village it is good enough for him on a plantation or anywhere else, regardless of the fact that the oft-repeated construction of a building, however cheap it may be in the first instance, does not make for economy in the long run, and that such a structure is from an hygienic point of view not suitable for human habitation.

Looking after the welfare of native labourers of the casual variety is on all fours with the housing allotted to them. There is no standard rule regarding the feeding of their employees amongst Europeans. Domestic servants and some in Government employment are given a small weekly allowance in addition to their pay for the purchase of such "delicacies" as they may fancy to augment their food. Casual labour is generally given rations of maize, meal, rice and beans. Few, if any, are given meat and fish as regular rations. Their food is cooked by themselves, no special arrangement for carrying this out being provided by the employers. The ideas regarding the feeding of their labourers is the same as that of their housing, so it is not surprising that employers complain of the small amount of work they get out of them.

Colonial Medical Reports.—No. 196.—Nyasaland Protectorate *(continued).*

Natives, in the main, are content with a hand-to-mouth existence, and when we take into consideration their natural indolence, coupled with debilitating diseases such as ankylostomiasis and ill-balanced dietary, it is not surprising that wages are small and industrial progress is slow. The first step towards an improvement in the existing state of affairs must be taken by the employers of labour. With improved housing and general conditions, better feeding and adequate medical care when sick, the output of work would be greater, the native would earn more money, and work of a continuous nature would hold some attraction for him.

The medical care of labour engaged in public and private works and in factories and workshops is, on the whole, satisfactory. There exists the usual difficulty of dealing with the native when he is sick, in that many are loth to take advantage of such facilities as are at their disposal for treatment. During the last few years his opportunities for receiving proper treatment have been much improved by reason of the greater number of native hospitals and dispensaries that have been erected and equipped. The treatment of natives on plantations varies according to the employer's attitude towards his natives generally. One can say that, on the whole, the treatment of natives on plantations during sickness is very far from satisfactory. If the plantation is situated near a hospital or dispensary there is some chance that the employer will do something towards assisting his sick employee. If situated far from skilled medical assistance the treatment of the sick will be of a most perfunctory nature, for few will even go so far as to employ a half-trained native dresser. Apart from the economic necessity for keeping all employees in a good state of health it should be made compulsory that all employers of labour make adequate provision for the medical treatment of their labourers.

(5) *Housing and Town Planning.*

The housing of Europeans in the highlands is, on the whole, satisfactory and as good as finance will allow. The same cannot be said for it in the highly malarious localities. In the latter even partially mosquito-proofed dwellings are not the rule, and where attempts have been made to mosquito-proof part of the house the result has generally been the creation of a mosquito-trap. The erection of proper houses, double-storied and wholly mosquito-proof, might be expensive, but it would be warranted by reason of the maintenance of the health and efficiency of those whose duties compel them to live in low-lying areas.

Zomba, because of geographical considerations, does not lend itself to suitable town-planning schemes, and houses are built on more or less suitable sites as they are required. The other townships show some efforts were made originally to lay them out on proper lines.

(6) *Food in Relation to Health and Disease.*

At Zomba and Blantyre meat inspection is carried out by the veterinary officers and, in their absence, by the medical officers of health. Apart from this any question that arises on the score of bad or doubtful food is a matter between the consumer and the purveyor, when, very occasionally, the medical officer of health is called upon to give his opinion. There are no public health laws in existence, and until such are adopted and a staff appointed to enforce them it is useless to discuss the subject of food so far as the control of its sale is concerned.

(B) Measures taken to Spread the Knowledge of Hygiene and Sanitation.

There are no measures taken to spread systematically the knowledge of hygiene and sanitation. Any efforts that are made are tentative ones on the part of the medical staff in the course of ordinary duties. As suggested, this matter could very well be dealt with in the schools.

(C) Training of Sanitary Personnel.

The system of training sanitary personnel inaugurated by the sanitation officer has been in abeyance during his absence on leave.

(D) Recommendation for Future Works.

(1) The employment of European sanitary inspectors at Zomba, Blantyre and Limbe.

(2) That adequate rating of the inhabitants be made to furnish means for the proper disposal, outside the townships, of all night soil and refuse.

(3) The strict segregation without the townships of all natives and Asiatics whose employment does not necessitate their being in the township over night. The former should be housed in properly laid out locations. With suitable sanitary arrangements provided in such locations these would prove valuable educative factors in instilling ideas of sanitation into the minds of those dwelling in them. The natives would enjoy greater freedom than they have now whilst living in close proximity to Europeans. This is the only means of rendering any sanitary measures to be carried out for the benefit of European populations effective. At present the so-called European townships are only European in name: for the fact that the ratio of Europeans to coloured is, estimated conservatively, one to six renders the title European absurd. The constant menace to the health of the Europeans from the presence of so many coloured people is obvious.

(4) The provision of pure pipe-borne water supplies to Zomba and Blantyre and, where possible, to other townships. Until such is made possible the adequate policing of all sources of water supply in the township is necessary.

(5) The employment of European or Asiatic inspectors of vaccination.

(6) The creation of a labour department to work in conjunction with the Department of

Native Affairs and the Medical Department to control and supervise by means of its labour inspectors the recruitment and treatment of all native labour.

Hospitals and Dispensaries.

Zomba.

European Hospital.—The number of admissions during the year was 64 and the daily average in hospital 2·2. There were 4 deaths. The out-patients treated numbered 82. In 1924 the in-patients were 56 and the out-patients 143. During the year one ward, which contained 6 beds, has been divided into two rooms, suitable for confinement cases.

Native Hospital.—The number of admissions during the year was 955 and the out-patients were 2,450. There were 22 deaths. In 1924 there were 464 in-patients and 4,118 out-patients, with 10 deaths. In 1924 the hospital was only open for 9 months, as it was started in April, which partly accounts for the much larger number of admissions in 1925; but apart from this, the new hospital is much more popular than the old one was. The decrease in the number of out-patients this year is accounted for by the opening of two dispensaries near by; these take a considerable number of minor cases which otherwise would attend the hospital.

Dispensaries.—Apart from the dispensaries which are ordinarily attached to the hospitals, there are 3 in the Zomba district. These 3 between them treated 5,762 cases. The Central Prison Hospital, the asylum and the military hospital are considered under their respective sections.

Blantyre.

European Hospital.—The number of admissions during the year was 128, with 6 deaths, as compared with 91 and 3 deaths in 1924. The out-patients were 177, as compared with 71 in 1924.

The Native Hospital at Blantyre was closed in 1925. This hospital was not large enough, was in disrepair and ill-equipped, so instead of building a new one it was considered more economical to send all natives requiring indoor treatment to the Blantyre Mission Hospital and to pay the mission a retaining fee for this work. The dispensary for out-patients is still carried on. This scheme has been in operation since April 1, 1925, and from then until the end of the year 54 patients were sent from the native dispensary to the mission hospital as in-patients. The out-patients treated were 2,203, as compared with 2,802 in 1924. There is one rural dispensary in the Blantyre district at Lirangwe, where 840 patients were treated, as against 720 in 1924.

Fort Johnston.

Native hospital: In-patients 132 with 9 deaths; in 1924 there were 211 with 6 deaths. Out-patients 1,021; in 1924 there were 720. There are four rural dispensaries in the district, which treated 2,092 cases, as compared with 2,215 during the previous year.

Mlanje.

Native hospital: In-patients 171 with 16 deaths; out-patients 657. In 1924 the numbers were 136 (6 deaths) and 334 respectively. This hospital is not nearly large enough and requires an extra ward. There are four rural dispensaries in the district, which treated 1,196 cases, as compared with 1,567 cases in 1924.

Dedza.

Native hospital: In-patients 87 (3 deaths) as compared with 55 (3 deaths) in 1924. Out-patients 1,092, as compared with 1,220 in 1924. There are four rural dispensaries in the district, which treated 5,846 new cases, as compared with 2,891 in 1924. The medical officer has given special attention to the treatment of yaws on the lake shore. Considerable success has attended the use of bismuth sodium tartrate.

Karonga.

Native hospital: In-patients 427 with 4 deaths; out-patients 5,034. In 1924 the numbers were 338 (2 deaths) and 4,955 respectively. There are four rural dispensaries which treated 5,562, as against 9,288 cases in 1924. One of the dispensaries was closed for a considerable time and this accounts to a certain extent for the falling off in numbers.

Kota-Kota.

A new hospital was opened here at the beginning of the year, and a medical officer has been stationed here since the middle of 1924. During the year 126 in-patients were admitted with 4 deaths. The out-patients numbered 4,261, as compared with 3,200 in 1924. There are four rural dispensaries, the fourth being opened towards the close of the year; 9,760 cases were treated at the rural dispensaries.

Port Herald.

Native hospital: In-patients 133 (6 deaths); out-patients 962. In 1924 there were 159 in-patients (7 deaths) and 855 out-patients. There are five rural dispensaries and 3,291 patients were treated at them, compared with 2,140 last year.

Lilongwe.

Native hospital: In-patients 171 (10 deaths); out-patients 1,947. In 1924 the numbers were 135 (7 deaths) and 1,437. There are four rural dispensaries, at which 1,442 cases were treated in 1925 and 918 in 1924.

Mzimba.

Native hospital: In-patients 127 with 8 deaths; in 1924 there were 119 with 4 deaths. Out-patients 2,322; in 1924 there were 2,174. There are five rural dispensaries, which treated 4,308 new cases, as compared with 4,741 in 1924.

Chikwawa.

Native hospital: In-patients 73 with 3 deaths, out-patients 1,532. In 1924 there were 26 in-patients with 1 death and 1,587 out-patients. The seven rural dispensaries collectively treated 4,460 cases as compared with 2,062 in 1924.

Fort Manning.

Native hospital: In-patients 103 (no deaths); out-patients 1,364. In 1924 the numbers were 53 (5 deaths) and 2,200 out-patients. There are three rural dispensaries and they treated 2,253 cases in 1925 and 1,917 in 1924.

Dowa.

Native hospital: 77 cases (2 deaths) and 2,320 out-patients. In 1924 there were 20 in-patients admitted (1 death) and 3,805 out-patients. There are four rural dispensaries, at which were treated 2,846 cases during 1925 and 1,611 in 1924.

Ncheu.

A sub-assistant surgeon has been posted at Ncheu since October, 1925. There is not a hospital, but 5 patients were treated as in-patients, being kept in two small native huts. The dispensary treated 1,085 cases. There are three rural dispensaries in the district, which treated 2,780 cases.

Of the 14 above-mentioned districts, the first 7 each have a medical officer, the remaining 7 each have a sub-assistant surgeon. Dowa and Ncheu had a sub-assistant surgeon for the last two or three months in the year only.

In addition to these districts there are 6 others which have not a medical officer or sub-assistant surgeon. They have rural dispensaries which are worked by native dispensers.

Prisons and Asylums.

Central Prison, Zomba.

The general health of the prisoners during the year has been good; many prisoners when first admitted are in a poor state of health owing to hookworm, bilharzia or poor feeding, but they improve considerably after a period of prison life. During the year there were 7 deaths, due to the following causes: lobar pneumonia, 3 cases; ankylostomiasis (and pellagra), 1; beriberi, 1; cardiac failure, 1; sarcoma of the ilium, 1.

The following is a return of the diseases treated during the year at the Central Prison:

Infective Diseases.—Dysentery (amœbic), 2; bacillary, 2; gonorrhœa, 6; leprosy (anæsthetic), 6; malaria (subtertian), 63; pneumonia, 33; syphilis, 6; tuberculosis, 3.

General Diseases.—Beriberi, 1; pellagra, 43; asthenia and debility, 10.

Nervous System.—Neuritis, 4; headache, 15.

Diseases of the Eye.—Conjunctivitis, 9.

Diseases of the Ear.—8.

Diseases of the Circulatory System.—Valvular disease of the heart, 3.

Respiratory System.—Bronchitis, 91; pleurisy, 5; asthma, 2; other diseases, 8.

Digestive System.—Caries of teeth, 11; sore throat, 16; tonsillitis, 10; dyspepsia, 3; enteritis, 9; hernia, 1; diarrhœa, 13; constipation, 43; colic, 5; other digestive diseases, 4.

Diseases of the Lymphatic System.—Adenitis, 3; lymphadenitis, 1.

Diseases of the Generative System.—Hydrocele, 2.

Organs of Locomotion.—Periostitis, 3; synovitis, 1; tenosynovitis, 6; fibrositis, 49.

Diseases of the Connective Tissue.—Cellulitis, 14; abscess, 10.

Diseases of the Skin.—Eczema, 8; boil, 29; herpes, 1; tinea, 42; scabies, 30; ulcer, 13; dermatitis, 2.

Injuries.—333.

Tumours.—Sarcoma, 1.

Parasites.—Schistosoma, 16; tænia, 4; ascaris, 1; ankylostoma, 28. Total, 1,032 cases.

Lunatic Asylum.

The daily average number of inmates during 1925 was 47·9, as compared with 40·7 in 1924 and 35·3 1923. Each year shows an increase in the number of admissions, and enlargement of the asylum is now required.

During the year 33 patients were admitted to the asylum hospital, as compared with 25 during the previous year. Attending the dispensary as out-patients there were 62, as against 78 in the previous year. The 5 deaths were due to: pneumonia, 2; pellagra and syphilis, 1; bilharzia, 1; and ankylostomiasis, 1.

Restraint was imposed upon 10 inmates; of these, 6 were restrained by seclusion (longest period 21 days) and 4 by handcuffs or leg-irons.

There were not any serious injuries. One violent inmate was slightly injured by a warder, who had to defend himself when attacked. There were 2 cases of slight injury to warders by patients.

Appendix I.

Medical Entomologist's Annual Report for 1925.

Concerning the tsetse-fly problem, steps were taken during the earlier part of the year to ascertain the final outcome of the field experiment undertaken towards the end of last tour for the purpose of ascertaining the degree to which it might be possible to effect the control of *Glossina morsitans* through the agency of a parasite, *Syntomosphyrum glossinæ*, attacking the puparia. A large number of these parasites, estimated at 277,179, were then distributed, the outcome being that by the end of March, 1924, the percentage of puparia found to have been attacked had risen from 0·05 to 12. In the course of the more recent work, up to March, 784 sound puparia were collected, 16 of which afforded the insects a parasitism rate of 2 per cent. There had been therefore a very decided effort on the part of nature to restore the balance. It might be possible to counteract this by maintaining a large laboratory output, but in all probability this would have to be ever-increasing, and as the results had not been so good in 1924 as had been hoped it was decided not to pursue the line of work further. A very fascinating possibility of effecting the control of the fly had been explored, which by itself had hardly proved radical enough, though it might have distinct value as an adjunct to other measures.

The value of the systematic dipping of an animal in arsenical solution of the usual strength (arsenite of soda 0·08 per cent. of arsenious acid) as a measure against tsetses and other insects biting it, an experiment initiated by Bevan in Rhodesia was tested. The rationale of the experiment lies in the fact that arsenic tends to be taken up by the superficial layers of the skin and to be absorbed into the blood, so that there would seem to be a possibility that a prejudicial and even lethal effect on biting insects might ultimately be produced. The result was entirely negative.

Glossina, certain mosquitoes, tabanid flies and ticks allowed to bite a goat that had been dipped thrice weekly over a period of three months seemed to be entirely unaffected, the tick (*Ornithodorus moubata*), indeed, breeding freely after more than one meal off the animal.

A further possibility—that of administering arsenic in gradually increasing doses to an animal over a long period of time with the idea of raising the content of the drug in its blood to a degree that it would have a lethal effect on biting insects—was investigated. The outcome was again negative, though, owing to one's repeated absences from headquarters, some uncertainty prevails as to the amount of the drug received by the animal, the administration being necessarily entrusted to native assistants.

The distribution of the tsetse-fly was studied in late July and early August in the Dowa and Lilongwe districts. In this region there had been for the past twelve years a steady advance of the fly from the north, from Rhodesia into Kasungu, thence into Dowa, and more recently into the salient of Lilongwe, between the Bua and Nambuma Rivers. A careful survey of the fly area in these regions having been made, a scheme, based very largely on the control measures applied by Mr. Swynnerton with such conspicuous success in Tanganyika territory, was submitted to the Administration. It consists, briefly, of:—

(*a*) The clearing of a wide strip of country across the line of advance of the fly.

(*b*) Intensive native settlement along the strip.

(*c*) Agricultural development of the strip and its gradual extension.

(*d*) Organized bush firing in the late dry season.

During November, when this fly area was again studied, an attempt was made to conduct an experiment in bush firing on a large scale against the pest. A full report on the subject was duly submitted to the Administration.

With regard to the malaria problem, the inquiry into the factors possibly involved in the causation of the annual epidemic rise of endemic malaria, which is so regular a feature in East Africa towards the close of the rains, was continued. The validity of the conclusion reached during the previous tour, that a very distinct seasonal occurrence of *Anopheles costalis* is probably the primary cause, received further support from a mass of data obtained during 1925, which again show that this anopheline was almost absent in the lower levels in the dry season, but was overwhelmingly abundant by the late rains, the other common species, *A. funestus*, showing no numerical increase throughout the year.

A study designed to ascertain the particular species of malaria parasite present in the peripheral blood of native children, and the phases present month by month throughout the year, was undertaken at Fort Johnston, for it was thought not impossible that there might be a dominance of one or other species correlated with the change of season, climatic conditions changing so very considerably, and that an increase of the forms of the parasite infective to anopheline mosquitoes might be associated with the numerical increase of the insects taking place by the late rains. It was hoped that it might be possible to secure for examination specimens of the blood of 30 selected native children, carriers of malaria, the same month by month, but, though they were brought forward punctually at first, it was impossible later to obtain specimens regularly in many cases, owing to indifference on the part of their parents, though suitably rewarded. During some months, therefore, less than half the number were secured, but these served to show in the case of quartan and subtertian malaria, the former in particular, that the various phases, including those infective to the mosquito, were present in one or other of the children throughout the year. Benign tertian malaria was found on three occasions only in the course of this and other investigations, in May, July and August, cold season months, concomitant with subtertian in a child who had previously shown quartan infection also; in July, again, with concomitant subtertian in a second child who had previously shown the same mixed infection, and in November, late dry season, in pure culture in a child whose antecedent history as to malaria was unknown.

A study of the amount and kind of malaria prevailing at various altitudes among the native community, with special reference to children possessed of all, or at least the majority of their temporary teeth, was initiated; the topographical distribution of anopheline mosquitoes being studied at the same time. Data obtained at the different elevations show striking contrast, and should have especial value in that there is very little tendency for native women with children to move from place to place. Thus in regard to South Nyasa district, in the Shire Valley—an elevation of about 1,600 feet—25 out of 50 specimens of the blood of native children examined in February, the late wet season, were positive as to malaria, 13 showing quartan infection; 5 subtertian; 4 a mixed infection; and 3 an infection undetermined. In the same locality in October, late dry season, the blood of 15 out of 34 examined was positive—10 with quartan, 3 with mixed quartan and subtertian and 2 with an infection undetermined. The anopheline vectors, *A. funestus* and *A. costalis*, were here abundant during the wet season, the latter being practically absent during the drought.

Colonial Medical Reports.—No. 196.—Nyasaland Protectorate (*continued*).

In regard to lake shore malaria, in the dry season with *A. funestus* only occurring sparingly, 2 specimens out of 33 showed parasites in the one case quartan and in the other benign tertian. In the hill country at Chowe's, at an elevation of 3,000 feet, 24 specimens of blood taken in the very early rains in December were entirely negative, *A. rhodesiensis* being the dominant anopheline, though by no means abundant, and *A. pretoriensis*, *A. funestus* and *A. costalis* occurring very sparingly. At Dowa, a rather higher elevation, about 3,800 feet, 59 specimens out of 60 taken at the same season in the early rains were negative, the exception being a quartan infection. Here none of the anophelines mentioned were obtained, but a species as yet undetermined but differing from *A. funestus* in its possession of bands on the legs, occurred in very great abundance.

A mass of data bearing on the bionomics of mosquitoes was obtained. A point of interest among them was that *Stegomyia argenteus* (*fasciata*) can not only sustain life, but will actually breed on a diet of reptilian blood.

The following papers were published during the year:—

(*a*) "An Attempt to Control *Glossina morsitans* by means of *Syntomosphyrum glossinæ*, Waterston," in the *Bulletin of Entomological Research*, vol. 15, January, 1925. (*b*) "The Seasonal Habit of the Common Anophelines of Nyasaland," in the same journal, vol. 15, April, 1925.

Appendix II.

Some Observations of Intestinal Parasites of Natives at Mlanje.

In the course of routine examination of fæces from natives attending Mlanje native hospital, either with signs of "dysentery," or in whose cases stool examination might assist diagnosis, so many different parasites were found that it seemed likely to be useful to extend the examination to normal individuals, with a view to obtaining information of the degree of infestation of the natives with intestinal parasites.

Thirty examinations of patients' stools having been made, an equal number from natives in normal health was taken for comparison, the police, warders and hospital attendants providing the specimens.

The material in each case was collected in special fæces-collecting pots, and was examined as soon as possible, usually within a few minutes of leaving the body and only very exceptionally after standing more than one hour.

The usual method for examination of fresh stools was used, viz., on a slide, in a drop each of normal saline and Gram's iodine (double strength) placed at suitable distances apart, an emulsion of the stool was made and covered with a cover-glass.

Each preparation was systematically searched, first for ova, &c., under the $\frac{2}{3}$ in. objective, any finding being confirmed under $\frac{1}{6}$ in., and then under $\frac{1}{6}$ in. for identification of entamœbæ, cysts, &c.; the staining effect of the iodine in some cases facilitated identification of cysts.

The following species were found:— *Entamœba histolytica*, free forms; *Entamœba histolytica*, cysts; "Entamœba"; "Cysts"; *Entamœba coli*, cysts; *Iodamœba butschlii*, cysts; *Giardia intestinalis*, free and cysts; Other flagellates, free; *Ascaris lumbricoides*, ova; *Ankylostoma duodenale*, ova; *Strongyloides intestinalis*, larvæ; *Schistosoma mansoni*, ova; *Tænia solium*, onchospheres; an Acarus (Tyroglyphus species).

In some cases, even in the iodine preparation, it was impossible to diagnose with certainty the species of a cyst as in the case of uni-nucleate cysts or when the nuclei could not be seen clearly enough to be counted; these have been recorded as "cysts."

In two cases, also, entamœba were present but presented insufficient characters to enable them to be identified certainly as *E. histolytica*, though this was suspected; they were therefore recorded as entamœbæ. But as in each case there was rapid recovery under emetine treatment, thus proving them clinically to have been *E. histolytica* infections, they have been included in the analysis of "dysentery" cases as amœbic dysentery.

An analysis of cases of "dysentery" based on both stool findings and clinical response to treatment records 18 cases: 8 cases of amœbic dysentery; 7 of schistosome dysentery; 2 of bacillary dysentery; 1 uncertain.

This analysis shows a great preponderance of amœbic and schistosome dysenteries over bacillary, and this is no doubt actually the case; but it must be borne in mind that the former type tend to be chronic infections and the latter acute, so that there is probably less chance of bacillary cases being seen at hospital owing to their inability to travel.

Diagnosis of bacillary infections must also be mainly clinical at present, for lack of cultural facilities, though the cell picture is of some assistance.

Helminth infections, based on the combined previous examinations, give the following results:— *Ascaris lumbricoides*, 21 cases; *Ankylostoma duodenale*, 17 cases; *Schistosoma mansoni*, 8 cases; *Strogyloides intestinalis*, 4 cases; and *Tænia solium* 4 cases.

The above must be regarded merely as minimal figures by reason of the method employed; had a concentration method been used much higher figures, for *Ascaris and Ankylostoma* at any rate, would undoubtedly have been obtained.

It is interesting to note that no ova of *Trichuris trichiura* were found.

The results obtained from the examinations are of sufficient interest to warrant the continuation of the work on a larger scale, chiefly to extend the information regarding the distribution of infections of public health importance, viz., "dysenteries" and hookworm; other parasites also to be noted for their general interest.

It is hoped that it will be possible to do this during the present year.

Appendix III.

Further Notes on Pellagra in Nyasaland.

Treatment by Thyroid Gland Tablets.—Over 100 pellagrins were treated with thyroid gland tablets during the year 1924, and out of this number there were only 8 recurrences during 1925. Two grains of thyroid extract were given to each patient once daily, in tabloid form.

Occurence of Pellagra in the General Population.—Three lunatics were admitted to the asylum with the disease well marked, and within two months from the date of their admission 9 fresh cases occurred in other inmates. One prisoner commenced his sentence with the disease. Two patients—one a woman who had been operated upon for an extra-uterine pregnancy, and the other a boy who was suffering from cretinism—developed the disease two months after admission into the Native Civil Hospital.

About 100 cases were noticed among natives in the district, who had not applied for treatment.

Period of Greatest Incidence of Disease.—The maximum number of cases occurred during the month of August.

New Symptoms Noted.—A feeling of dizziness particularly marked on rising in the mornings.

Result of Blood Examinations.—Forty blood examinations were made, and in all cases there was a reduction in the number of red cells, varying from 500,000 to 1,000,000. The percentage hæmoglobin varied from 40 to 70. A marked eosinophilia was present in most cases.

Adequacy of Prisoners' Diet.—The calorific value of the diet was found to be quite adequate, and averaged 3,000 calories per prisoner per diem. Fresh vegetables were issued every day.

Investigation of Possible Insect Carriers of the Disease.—Several prisoners with pellagra gave a history of having been bitten by a small fly, previous to the onset of the condition. Some of these insects were captured and examined for me by Captain C. Smee, Entomologist to the Agricultural Department, Nyasaland Government. He reported that they were flies of the Simuliidæ family. On further investigation in the fast-flowing streams in the vicinity of the prison, numerous larvæ and pupæ were found, most plentiful during the month of June. There were points both in favour and against Simulians carrying the disease.

F. W. Dry, Entomologist, Kenya Colony, describes what he terms simulian disease in the *Bulletin of Entomological Research*, vol. 12. The disease described bears a resemblance to pellagra, e.g., "The chief symptom is that the skin is in folds. Many of the affected people I saw were able to carry on their usual activities, but some looked to be in quite a feeble condition. Poor sight or even blindness is stated to be caused by the disease occasionally. I obtained slides from three men who had lived in the infested country, and said they had had the disease for about 40 years, and 20 per cent. eosinophilia was found in the blood of each of the three individuals."

Influence of Diet in the Ætiology of the Disease.—Diet appears to be only important in pellagra in so far as food deficiency, with absence of vitamin C content and carbohydrate excess, lowers bodily resistance.

Enlargement of the Parotid Gland.—No enlargement of the parotid gland has been noticed in the series of pellagra cases that have come under my observation.

Appendix IV.

Some Notes on the Treatment of Yaws in Nyasaland.

Yaws has for years been prevalent in the low-lying area bordering the lake shore. Prior to the establishment of the rural dispensaries little was done to combat the disease, but during the years 1922-3-4 the dispensaries were supplied with Castellani's mixture, and a considerable number of natives were treated, both at the dispensaries and in their villages. The results, on the whole, were disappointing, particularly in regard to the tertiary cases; the secondary cases derived considerable benefit, but there were many relapses and imperfect cures.

In August this year treatment by intramuscular injection of 10 per cent. solution of sodium bismuth tartrate was commenced in two particular areas—at Mua and Ntakataka. At Ntakataka treatment was carried out by a native dispenser who was not very reliable, either as regards his records or his methods; at Mua by the Fathers and Sisters of the Roman Catholic Mission who were very enthusiastic and kept accurate records. The results have been most successful, and the natives, once they realized the value of the new treatment, flocked to the dispensaries. No relapses of apparently cured cases have so far occurred, and there seems to be very little doubt that by extending this treatment to other areas the disease could be entirely eliminated. Usually, in any scheme for the treatment of disease on an extended scale, the chief difficulty is with the natives themselves, who will not voluntarily come up for treatment and run away when they are offered treatment in their own villages; but in this case the results are so immediate and the method so free from pain or the necessity for any self-denial that patients appear at the treatment centres with as much alacrity as if they were about to receive their wages.

Cases Treated.

At Mua 382 males and 429 females were treated, at Ntakataka 86 (sex not recorded), and at Dedza 1 male and 1 female.

The large majority of these cases were secondary, but there were several cases of chronic deep ulcers of the legs, which were probably due to yaws and which yielded rapidly to treatment. One striking case of tertiary yaws, in which bone symptoms were a prominent feature, the patient being almost crippled, improved at once under treatment; the pain disappeared and the man looked and declared himself well after the third injection.

Colonial Medical Reports.—No. 197.—Trinidad and Tobago.

ADMINISTRATION REPORT OF THE SURGEON-GENERAL FOR THE YEAR 1925.

Port Health Work.

Quarantine was maintained against Venezuela and Brazil during the whole year; against New York for two months on account of small-pox, and against Cayenne from July to December on account of alastrim.

The number of ships visited was 1,008; 460 were steamers, and 548 sailing vessels, mostly sloops from Venezuela.

Fumigation and disinfection was done in 662 vessels, while 503 packages of baggage were fumigated.

During 1925, 5,597 passengers and 36,794 crew —total 42,391—were inspected; of these 1,632 were kept under surveillance.

Hospitals, Dispensaries and Venereal Clinics.

There is in general a steadily increasing demand on the services of these. In 1910-15, the average number of patients in the three colonial hospitals were as follows: 278, 105 and 33, whereas in 1920-25 the corresponding figures are 338, 135 and 48. Similarly in the six district hospitals the total was 124 in 1910-15, and 159 in 1920-25.

The gradual extension of health offices, principally in the southern and western districts, to meet the spreading population in more recently settled areas has led to a large increase in out-patient treatment. The reorganization of the health office in Port of Spain and removed to the Colonial Hospital as an out-patient department in 1921, has had similar results. Whereas in 1916 out-patients attending all health offices numbered 57,000, in 1925 they numbered 88,000.

The training of nurses continued, special attention being given to this important work. The course for medical and surgical nurses is three years, and for midwives two years, of which the greater part is spent in the general medical and surgical wards of the hospitals.

Fifty-seven candidates were presented for examination, and 41 passed.

At the Colonial Hospital, Port of Spain, the X-ray equipment was brought up to date and put in commission; the administration block redivided to facilitate emergency work; the laundry was extended, and the constant hot water supply apparatus renewed.

At the Colonial Hospital, Tobago, electric light and a piped water supply has been installed throughout.

In the district hospitals, the following improvements were made: St. Joseph, sewerage installed in place of pail system; Tacarigua, sewerage extended to all hospital buildings, and laundry enlarged; Arima, renewal of electric light batteries; Couva, a new concrete cistern and a new mortuary; Princes Town, pipe water installed and sewerage in place of pail system.

Up to 1922 it had been found difficult to maintain an adequate quantity of milk of satisfactory purity; in consequence large quantities of condensed milk were used, especially at the Colonial Hospital, Port of Spain.

Since 1922 the Director of Agriculture and his officers have kindly extended the milking herd at the Government farm until, in 1925, a full supply of high-grade milk was available, not only at the colonial hospitals, but also at the other medical institutions.

This has raised the cost of food per head per diem by 65 per cent.

Dental clinics were opened for the first time this year at the colonial hospitals, Port of Spain and San Fernando. At these 612 people were treated. Development will gradually take place according to the results of experience.

Venereal clinics continued steady work at Port of Spain and San Fernando. Attendance tends to become more regular and continued.

Asylums.

At the St. Ann's Lunatic Asylum there is a steady general tendency towards a reduction in numbers.

Every effort is made to obtain patients for institutional treatment early in the disease, while physical condition is still good. As a result of this policy long continued, the recovery rate each year is a satisfactory one.

The leper asylum is still divided, part being at Chacachacare and part at Cocorite. In 1926 the building at the former will be completed and the final transfers will take place.

The daily average is at present decreasing

The increase reached a maximum of 543 in 1919 as a result of the leper ordnance of 1913. Since that year reduction has set in, the average for 1924 being 452, and for 1925 432.

This reduction is due to three causes (*a*) reduction in admissions, now about 100 a year instead of 150-200 a year; (*b*) repatriation of East Indian lepers to India at their request, 147 have been returned between 1921-25; (*c*) discharge of those in whom symptoms of active disease have disappeared—31 such in 1924-25.

Absconding is much reduced, from about 70 to 80 a year to 16 in 1925.

There is now being developed an active and thorough campaign of treatment. This consists mainly of (*a*) specific treatment with hynocarpus oil, (*b*) careful treatment of debilitating diseases, and (*c*) attention to exercise, diet, &c.

The house of refuge continued very full throughout the year. No changes or alterations were carried out in view of the possibility of removal elsewhere.

SCIENTIFIC.

Special investigations beyond ordinary routine work were conducted by the Government bacteriologist into: (*a*) the bacteriology of human and animal fæces in relation to water supplies, including the determination of *Bacillus coli* and *B. aerogenes;* (*b*) the distribution of bovine tubercle bacillus in human beings; (*c*) an outbreak of abortion amongst cattle; (*d*) an outbreak of botulism amongst cattle.

The routine investigations numbered 4,577, of which Wassermann test numbered 1,601, malarial examination 202, Widal tests 985, tubercle sputum 770, diphtheria examination 185, and examination for amœba 127.

In addition 5,593 rats were inspected for plague, with no infection.

Thirty-four thousand six hundred and seventy-one doses of antityphoid vaccine (typhoid and paratyphoid A and B), were made and issued.

Colonial Medical Reports.—No. 198.—Trinidad and Tobago.

ADMINISTRATION REPORT OF THE MEDICAL INSPECTOR OF HEALTH FOR THE YEAR 1925.

POPULATION.

The mid-year population has been estimated by the Registrar-General as 383,422.

BIRTHS.

The number of births registered was 12,701—6,450 males and 6,251 females—equivalent to a birth-rate of 33·12 per 1,000 of population. This rate is slightly below (0·54) that of last year, but is 1·92 above the mean (32·2) for the preceding 10 years.

DEATHS.

The number of deaths registered was 7,888—4,267 males and 3,621 females—equivalent to a death-rate of 20·57 per 1,000 of population. This rate shows a slight increase (0·55) on that of last year, which was the lowest on record, but a decrease of 1·66 on the mean (22·23) for the preceding 10 years.

NATURAL INCREASE OF POPULATION.

The natural increase of population, *i.e.*, excess of births over deaths, was 4,813.

This year's figure, though smaller than the two preceding years, indicates the maintenance of a satisfactory growth of population.

INFANTILE MORTALITY.

Of the total deaths registered 1,708 were of children under one year of age. The infant mortality rate (*i.e.*, proportion of the deaths under one year to the 1,000 births in the same period) was 134·47.

This figure breaks the record of the steady decline of the rate since 1920, but the rise is probably temporary, and due to the more than usual unfavourable conditions during the third quarter of the year.

No branch of the Child Welfare League was opened during the year. The League continued its activities in the following areas: Urban—Port-of-Spain and San Fernando. Rural—St. James, St. Joseph-Caroni, Sangre Grande, Toco, Cedros, Tobago.

INFECTIOUS DISEASES.

ENTERIC FEVER.

834 cases were notified, with 205 deaths. The summary of the distribution for the last five years shows a marked increase in the prevalence in the southern half of the island which has hitherto been relatively lightly affected.

The seasonal incidence shows that the majority of the cases occurred during the wet season following the mean curve as plotted out for the five years 1909-1923.

In Port-of-Spain there was also a return to the mean—the months of highest prevalence being January, with 26 cases, and September, with 31 cases.

Investigation of the distribution showed that this year's high total was principally due to local outbreaks in new areas following on the introduction of infection from localities in which the disease is more or less endemic. The measures of prevention detailed last year were continued. Further experience has strengthened the opinion expressed last year of the value of preventive inoculation.

There is ample evidence that in outbreaks in rural districts where families housed in the usual labourer's hut live or sleep in one room without any attempt at the separation of the sick from the healthy, this measure is of the greatest service in controlling the spread of the disease.

The importance of early notification is generally recognized, but the wide prevalence of malaria during the period of the seasonal prevalence of enteric fever, and the social and physical circumstances naturally present in rural areas with a scattered population, hamper its application. It is evident, however, that there is improvement in this direction.

Colonial Medical Reports.—No. 198.—Trinidad and Tobago *(continued).*

TUBERCULOSIS.

There were 519 cases of pulmonary tuberculosis and 439 deaths registered. Of the total notifications 186 were from Port-of-Spain and 270 from the other towns and large villages in the following order: San Fernando 49, St. Joseph 31, Diego Martin 30, Couva 26, Erin-Siparia 26, Princes Town 23, Manzanilla 22, Tacarigua 18, Tobago 16, Ortoire-Moruga 15, and Naparima 14. 25 cases of tuberculosis other than pulmonary were notified.

PNEUMONIA.

399 cases with 219 deaths were notified—113 from urban and 277 from rural districts. The cases occurred generally over the Colony throughout the year.

CHICKEN POX.

60 cases were notified—35 from urban and 28 from rural districts. There was no death.

DIPHTHERIA.

48 cases with 5 deaths were notified—21 from urban and 27 from rural districts.

PRINCIPAL CAUSES OF DEATH.

MALARIA

retains its position as the chief cause of death and accounted for 791 deaths. This figure, though 34 above that of last year, is 29 below the mean of the preceding six years.

DIARRHŒA AND DYSENTERY.

During the months of June and July there was widespread prevalence of diarrhœal diseases. The condition was characterized by acute onset, absence of or only slight rise of temperature, profuse diarrhœa—the stools generally water and frequently bloodstained, and caused many deaths, chiefly among children and elderly persons. It appeared to be related to drinking water, but began at the end of the dry weather and before the onset of the rains, and occurred in districts with different sources of supply, *i.e.*, streams, wells and ponds without apparent special incidence in relation to any particular source.

The total mortality from these two causes for the year shows a substantial increase over that of last year. The unfavourable effect of the outbreak is apparent in the high mortality figures of the third quarter of the year.

PUBLIC HEALTH.

LEGISLATION.

The following bye-laws were approved by the Board and confirmed by the Governor in Executive:

Bye-laws made by the Port-of-Spain City Council with respect to match factories and workshops.

Ophthalmia neonatorum was declared an infectious disease under section 100 of the Public Health Ordinance No. 15 of 1915 on May 21, 1925.

TRAINING OF SANITARY INSPECTORS.

A course of lectures was given from May to July and on its termination a tutorial class with demonstrations covering the subjects. A qualifying examination was held in September; 9 candidates sat; 5 qualified and were awarded the certificate of the Board.

ANTI-MALARIAL WORK.

Quinine in tablet form at the low cost of 1 cent for 5 grains was placed on sale at post offices in country districts. The Postmaster-General and his staff have taken a keen interest in this measure, and through their ready co-operation large quantities of the drug have been sold.

At the same time and as an educative effort a lecture written by the Hon. Surgeon-General and illustrated by lantern slides has been given at several centres of population by the Medical Inspectors and Medical Officers of Health.

ANKYLOSTOMIASIS CAMPAIGN.

There has been no interruption of this work. Two units, of two men each selected from the staff of the Rockefeller Commission, were organized and during the year have worked in the districts of Diego Martin, Cedros and Toco. These four officers are qualified Sanitary Inspectors and undertake sanitary duties in co-operation with the Sanitary Inspector of the district.

THE MODEL VILLAGE OF BRIGHTON-LA BREA.

"The usual high standard of sanitation was maintained in the bungalow area during the year. During November and December there was an extension of the New Jersey Model Village, one bachelors' barracks and six family barracks having been built. The New Jersey Commissariat was also enlarged, and a model electric bakery added—whilst the facilities for recreation and enjoyment were enhanced by the addition of a cycle track and football and cricket field. The New Jersey Village now consists of 36 cottages, 15 family barracks and 11 bachelors' barracks. The general health of the residents has been very good, and with the exception of the usual malarial epidemic during August and September there has been comparatively little sickness of any kind." (Extract from Dr. de Verteuil's report.)

WATER SUPPLY.

The Tobago Waterworks, which were in full operation during the latter part of the year, was formally opened by His Excellency the Governor on April 21, 1926. The Sangre Grande Waterworks were extended to the Manzanilla district.

VENEREAL DISEASES.

The Venereal Clinics at Port-of-Spain and San Fernando continued in operation throughout the year—a summary of their work is given below.

SUMMARY.

The record of the year was somewhat disappointing, but the decline from the record of last year is

slight, and a broad survey supports the opinion that this is temporary.

SUMMARIES OF REPORTS OF THE MEDICAL OFFICERS OF HEALTH.

Diego Martin District.

The district shared in the typhoid outbreak, 50 cases having been reported. The usual measures were taken for prevention, including inoculation, which I am informed was extended to the schools. No other disease was sufficiently prevalent to merit mention.

Overcrowding, primitive customs and filthy habits favour the spread of infectious diseases.

Efforts are being made for the provision of sanitary cowsheds, and shops are regularly inspected to ensure wholesomeness of food for human consumption. The sale of vegetables and fish is conducted under shop shelters in St. James. It would be advisable to provide an independent structure for that purpose.

Water appears to be sufficient and of good quality. It is partly pipe-borne, as in the larger villages and the suburb of St. James, or partly collected from springs and wells. Supply is normally constant, but becomes intermittent during a drought. The streams are not perennial. The usual pollution by clothes washing, &c., obtains.

St. Joseph District.

Infectious Diseases.—The following cases were notified: Enteric fever 80, pulmonary tuberculosis 27, pneumonia 23, chicken pox 3, diphtheria 5, ophthalmia neonatorum 2.

There were no infectious diseases to any extent with the exception of enteric. Of this there were 80 cases as compared with 91 last year. A point of interest is that *the majority of the cases occurred in the low-lying districts* of Caroni, Barataria, El Socorro, which are also the most thickly populated and least sanitary areas.

3,039 inoculations against enteric were done during the year.

Sanitation.—The sanitary work was efficiently carried out by the Sanitary Inspector, and there is quite appreciable improvement in latrine and cowsheds.

Privy Accommodation.—Cesspits are in general use. 325 fresh pits were opened during the year; 17 concrete pits were emptied and disinfected.

Anti-Mosquito Measures.—These were carried out within the capacity of the funds available and the education of the people in this direction continued. Pools and drains were regularly oiled.

Cowsheds.—Twenty-five were concreted, making a total of 115 concreted cowsheds in the district.

Arima Rural District.

Twenty-four of the total of 76 deaths recorded were children under five years of age. The chief causes of death were disease of the alimentary system 14, disease of the respiratory system 11, malaria 9, disease of the kidneys 6, dysentery 4, tuberculosis, pneumonia and cancer 3 each.

Infectious Diseases.—The cases notified were: Enteric fever 2, pneumonia 5, tuberculosis 2, diphtheria 1.

Other Diseases.—Malaria was prevalent throughout the year, but least so during the dry season. In August and September a good many cases of malignant malaria were seen.

Yaws seem to be gradually dying out. Many cases of chronic ulcers were injected, under the supposition that yaws may have been an ætiological factor, with satisfactory results.

Ankylostomiasis continues very prevalent.

Privy Accommodation.—Most of the time of the Sanitary Inspector is taken up with this work. 345 new cesspits were built during the year, and a large number of those already existing were cleaned and disinfected.

Anti-Mosquito Measures.—The usual minor measures were carried out.

St. Andrew District.

General Health.—Less favourable than in previous years.

Infectious Diseases.—Typhoid fever 78, pneumonia 51, consumption 17.

Typhoid Fever.—The number of cases in the previous year was 28. To a considerable extent the increase was due to the introduction of cases from outside the district, viz.: Tunapuna, San Juan and Las Lomas. 34 cases were definitely traced to these sources.

Preventive inoculation was largely employed. During the year 6,134 persons received 13,329 anti-typhoid inoculations.

Other Diseases.—Dysentery—103 cases against 71 in the previous year. The cases were not limited to any one part of the district, but were scattered about indiscriminately and occurred more or less throughout the year.

Malaria.—The chief disabling disease. 2,823 cases were treated, the greatest number occurring in the months of July, August, September and October.

Influenza.—75 cases of which 57 occurred in the months of January, February, March and April.

Pneumonia.—51 cases, more or less distributed throughout the year.

Food and Drink.—Conditions as regards milk and food for human consumption were normal.

Water Supply.—No difficulty in obtaining water anywhere. The Sangre Grande Waterworks were extended to Manzanilla—a boon to the inhabitants of that part of the country.

Drainage.—The drainage of Sangre Grande Town is in the same deplorable state.

Privy Accommodation.—Pit closets chiefly.

A new dumping ground was opened on January 1, 1926, at a further distance from houses to lessen the nuisance of flies.

Chaguanas District.

General Health.—There was no epidemic or any case of disease unusually grave.

Infectious Diseases.—Five cases of enteric fever occurred at Charlie Village and Bejucal and two cases of pulmonary tuberculosis at Endeavour, but there was nothing of an alarming nature.

Other Diseases.—Malarial fever and ankylostomiasis were generally prevalent.

St. David District.

General Health.—There were no circumstances affecting or threatening the health of the district.

Infectious Diseases.—The following cases were notified: Pneumonia 2, pulmonary tuberculosis 6, chicken poz 2, diphtheria 1, enteric fever 2, ophthalmia neonatorum 1.

Both cases of enteric fever occurred at Cumana. One case arrived in the district of San Juan suffering from continuous fever; the other and later case never left the district. All the contacts were inoculated.

The case of diphtheria and all the cases of the pulmonary tuberculosis were sent to the Colonial Hospital.

Water Supply.—There are no waterworks in the district. Rain and river water is used. The quality throughout is good and at Matelot and Grande Riviere the supply is abundant all the year round. There is a diminishing supply at Sans Souci and Cumana during the dry season, at which time the people depend on the Betty and Sans Souci rivers and the Tompire River. At Toco village the people are badly off for water during the dry season. They depend on a well and the Basin Galape River.

Drainage.—Toco village especially calls for improvement by way of the opening of the mouths of such rivulets as (1) Patience Ravine, (2) Garcie Ravine, (3) El Toco River.

Privy Accommodation.—The privy cesspit system in the district is fairly good. There are approximately 970.

Disposal of Refuse.—In Toco Village a scavenging cart is employed to collect and dump the refuse into the sea.

Gran Couva District.

November 24 to December 31, 1925.—During the period no cases of infectious disease were seen. The district is hilly with few or no collections of standing water.

Naparima District.

Enteric Fever.—The outstanding feature of the year was the increased prevalence of enteric fever. 102 cases were notified as against 32 in 1924. The measures adopted for the control of the disease were —(1) removal of cases to hospital; (2) improved latrine accommodation and disinfection of premises generally; (3) inoculation.

The water supply is very unsatisfactory, the chief source of supply being ponds.

Princes Town District.

Water supply of the Princes Town Waterworks is good in both quality and quantity. In areas beyond this water supply rain water is collected during the rainy season in pails, barrels, coppers, tanks, cisterns, &c., which in the absence of screening and fishes serve as admirable breeding places for mosquitoes. In the dry season ponds and shallow wells supply the water, the quality and quantity of which are unsatisfactory.

Closet Accommodation.—Number of privy cesspits increased by 252 new privies during the year. A few w.c.'s and septic tanks exist at Ste. Madeleine, Reform Estate, Pointe-a-Pierre, and Princes Town.

Milk Supply.—The bye-laws are being enforced. 192 visits of inspection were made to dairies and cowshads during 1925. The number of registered dairies and cowsheds was 52. 51 licences were issued to vendors of milk.

Typhoid Fever.—The majority of cases of typhoid fever could be assigned to impure supply in the areas not within the reach of the Princes Town Waterworks. The highest number of cases occurred during the month of December and the areas affected were the villages of St. Mary and 5th Company.

Fever cases occurred at Cedar Hill and Chirkoo Village, where extensive inoculations were carried out in 1924.

Inoculation of contacts with the necessary isolation of cases and disinfection of premises and clothing were carried out.

Malaria.—During the year the Government placed at country post offices quinine tablets for sale to the public at reasonable prices, one 5 grain tablet costing one cent.

Lantern lectures were delivered by the Senior Assistant Medical Inspector of Health explaining the prophylaxis and treatment of malaria.

The use of quinine was strongly advocated.

Ortoire-Moruga District.

(*a*) General prevalence of bacillary dysentery from May to September, incidence greatest at New Grant, Monkey Town and Torrib Trace.

(*b*) *Water Supply.*—Princes Town Waterworks up to 11½ mile post on the Naparima-Mayaro Road. In other parts of the district ponds are the sources of supply, quantity and quality unsatisfactory.

(*c*) *Infectious Diseases.*—There were 26 cases of enteric fever and 18 of pulmonary tuberculosis.

(*d*) *Chief Causes of Death.*—Malaria, dysentery, chronic nephritis, senility, congenital debility, gastro-enteritis, pulmonary tuberculosis and ankylostomiasis.

Of these malaria is *facile princeps*. The next 5 diseases occupy an intermediate position between malaria and the last two, viz., pulmonary tuberculosis and ankylostomiasis, which are each responsible for about half as many deaths as malaria claims.

Erin-Siparia District.

(*a*) The conditions favourable to the existence of malaria are present in all parts of this large district.

Ankylostomiasis, though prevalent, has not been responsible for many deaths.

(*b*) 34 cases of enteric fever were reported. Of these roughly half were genuine cases. Inoculation of contacts was effected wherever possible.

There were many cases of dysentery in the Penal area.

(*c*) Water Supply is inadequate and unsatisfactory.

(*d*) The work of the satisfactory disposal of sewerage has been carried out with some vigour. The privy accommodation is much in advance of last year.

(*e*) *Scavenging* has been systematically carried out at Siparia, Oropouche, Fyzabad, Erin and Penal.

Brighton-La Brea District.

Brighton.—The usual high standard of sanitation was maintained in the bungalow area at Brighton during the year. During November and December there was an extension of the New Jersey Model Village, one bachelors' barracks and six family barracks having been built. The New Jersey Commissariat was also enlarged and a model electric bakery added—whilst the facilities for recreation and enjoyment were enhanced by the addition of a cycle track and football and cricket field.

The New Jersey Village now consists of 36 cottages, 15 family barracks, and 11 bachelors' barracks.

The general health of the residents has been very good, and with the exception of the usual malaria epidemic during August and September there has been comparatively little sickness of any kind.

La Brea.—There has been a marked change in the general appearance of the Government New Village during the year owing to the construction of numerous houses in accordance with an agreement in Corbeaux Town and Dundonald's Village—Ladysmith, where several so-called houses have been allowed to tumble to pieces in consequence.

The hopes once entertained of an early reconstruction of Corbeaux Town and Ladysmith have not yet been realised, and these filthy villages still stand as disgraceful landmarks of the woeful lack of sanitation once prevalent in bygone days all over the colony, landmarks made all the more prominent in contrast to the neighbouring Government New Village and the Model Village of New Jersey.

Infectious, &c., Diseases.—Malaria was endemic as usual, but became epidemic from July to November.

Measles and mumps were very prevalent from March to September.

Water Supply.—The wells at the Government New Village have been cleaned and connected up together and a fairly plentiful supply of good potable water is now obtained.

A small pipe leading from the wells to a site near the R.C. schoolhouse would easily supply the New Village and Corbeaux Town residents and should be an inexpensive undertaking.

Privies.—Very useful work has been carried out by the Sanitary Inspector. 194 cesspits and 130 privies have been built during the year.

Cedros District.

Malaria and ankylostomiasis are the two most prevalent diseases.

The district abounds in lagoons and swamps of large areas.

Water Supply.—The population depends on ponds, tanks, barrels. In the dry season there is much hardship. This district is badly in need of a constant source of satisfactory potable water.

Sewerage Arrangements.—This year has seen much improvement in the privy arrangements. Many new cesspits, 50 have been constructed according to the model supplied by the Central Board of Health. Few pails remain. With the disappearance of the pail privies, much of the beach pollution, which has been a great nuisance in the past, will happily cease.

Infectious Diseases.—Pulmonary tuberculosis 8, lobar pneumonia 3, ophthalmia neonatorum 2. There were no cases of enteric fever.

Dysentery.—A severe outbreak occurred in August and September, mainly in Bois Bourg. The drinking of pond water appeared to have a casual relationship to the outbreak.

Hookworm Campaign.—From October two hookworm officers of unit B. have been operating with the district hospital as headquarters. The work has been progressing very favourably, the inhabitants availing themselves readily of the opportunities for examination and treatment. The whole of Bonas and Ste. Marie Villages had been treated by the end of the year.

Scarborough District, Tobago.

The principal causes of death were—Malarial fever 15, cardio renal 17, senile and associated conditions 22, pneumonia 11, pulmonary tuberculosis 4, cancer 9.

Infectious Diseases.—4 cases of enteric fever came under observation. Total admissions to hospital were 6, so that the figures for the whole island, even admitting that a few cases might have escaped detection, were very satisfactory. For 3 previous years 50, 37 and 29 cases were treated.

Our routine measures, the only that appear worth carrying out, viz.: (1) immediate isolation in hospital, (2) inoculation of contacts and others who might be induced to come forward.

Other Diseases.—Malarial fever incidence remains undiminished. Two cases of malignant malaria occurred in the Scarborough District. The distribution of quinine from the post offices does not appear to have affected the situation to any appreciable extent. An anopheles survey has been carried out and breeding places charted, but the situation is a changing one from year to year, and favourable results can hardly be expected with the small means at our disposal.

Colonial Medical Reports.—No. 198.—Trinidad and Tobago *(continued).*

Ankylostomiasis.—Severely infected cases have remained a rarity in the district. All suspected adult cases are now treated with CCl_4. Although I have used maximum doses, I have seen no ill results.

Yaws.—The use of the sod. bism. tart. preparation was continued. Recurrences do occur, but in no larger a proportion of cases than with N.A.B. It is well tolerated by children, in whom is rarely seen a case of stomatitis, although there have been a few troublesome cases of the latter in adults.

Sanitation.—The usual rounds of inspection have been assiduously carried out by the Sanitary Inspector during the year.

Food and Drink.—Supervision of milk supply was confined to inspection of milk cows and vendors. Shops, bakehouses, &c., have been regularly inspected.

Water Supply.—It is a pleasure to record that a pipe-borne water supply has been in operation throughout the district during the latter half of the year.

Drainage and Anti-Malarial Measures.—During the year only minor anti-malarial work has been possible. A small section of drain in the town has been concreted. It is recommended to continue this work as a useful permanent measure. The neighbouring swamps and gullies have been attended to by the prison gang and oiling carried out wherever indicated.

Privy Accommodation.—The improvement of privies in accordance with the new Privy By-laws is being systematically carried out.

Roxborough District, Tobago.

General Health.—There was no epidemic prevalence of infectious diseases.

Infectious Diseases.—Three cases of enteric occurred during the year.

Other Diseases.—Malaria and yaws are the most prevalent diseases.

Sanitation.—Minor anti-malarial measures were carried out throughout the year.

Plymouth District, Tobago.

General Health.—There has been no epidemic in the district.

Infectious Diseases.—Pulmonary tuberculosis and enteric fever appeared occasionally; the latter never gave cause for worry.

Other Diseases.—Whooping cough was prevalent during the last two or three months of the year. No deaths were due to it.

In hot months there were a few cases of dysentery in adults.

The absence of gastro-intestinal trouble in infants is ascribed to the educational measures propagated by the nurses of the Child Welfare League. There is no doubt that much good work is being done by the League.

Sanitation.—The Sanitary Inspector paid the usual visits to premises, &c.

Food and Drink.—Bakehouses were regularly inspected and bakers have to procure a certificate of fitness of health before they are allowed to engage in the trade.

Slaughtering in country districts is not so easily controlled, some supervision is nevertheless given.

Water Supply.—Part of the district has been blessed with a water supply. It is to be regretted that the promising villages of Mason Hall and Moriah were not included in the scheme.

Drainage and Anti-Malarial Work.—Anti-malarial work due to a pitiful belief in temporary measures gave little result.

Privy Accommodation.—169 new privies built and 177 cesspits were dug. Two schools, the Adelphi E.C. and Parlatuvier E.C., have repeatedly failed to comply with notices served them, and the managers' promises have been repeatedly broken.

Antenatal work is being attempted and already some good has been achieved, many expectant mothers bringing specimens of urine for examination.

VENEREAL DISEASES CLINIC, PORT-OF-SPAIN.

The following are the statistical figures of the Venereal Diseases Clinic at Port-of-Spain for the year ended December 31, 1925: The number of persons dealt with during the year and found to be suffering from (*a*) syphilis, (*b*) gonorrhœa, or (*c*) conditions other than venereal were 1,481 males and 901 females.

The number of doses of (*a*) arsenobenzol compounds was 1,898, (*b*) bismuth preparation 1,148, and (*c*) mercury 1,090. The total number of attendances of syphilitic patients was 4,136. The number of irrigations with potassium permanganate and oxycyanide of mercury was 26,985. The arsenobenzol compounds used were neodiarsenol and neosalvarsan. The bismuth preparation used was sodium potassium bismuth tartrate. The mercury used was mercury cyanide.

The attendance was regular, but there are a fair number of persons who cease to attend before completing the first course of treatment. It is regrettable to state that there were only fifteen syphilitic cases discharged as cured, or at least gave a negative Wassermann reaction after treatment. The injection of sod. pot. bismuth tartrate had to be discontinued on account of the pain and induration it caused, and in a few cases abscess formation. The ill effects after injections of neosalvarsan were not severe. The most frequent sequelæ noticed were vomiting, rise of temperature, and vaso-motor disturbances.

VENEREAL CLINIC—COLONIAL HOSPITAL, SAN FERNANDO.

The Venereal Clinic was opened daily for the free treatment of venereal disease. The Assistant Resident Surgeon attended to the male patients on Mondays and Wednesdays, and to the female patients on Thursdays and Saturdays.

The following diseases were treated: Syphilis,

167 males and 62 females; gonorrhœa, 123 males and 195 females; granuloma, 3 males.

The following injections were given: Intravenous N.A.B., 1,236; intramuscular mercury, 846.

The attendance has definitely improved and patients persevere more in the treatment, the average number of N.A.B. injections per patient being 5·4 and mercury 4. This means that about 75 per cent. of those treated had a satisfactory course of treatment.

Colonial Medical Reports.—No. 199.—Cairo.

REPORT OF THE MEDICAL OFFICER OF HEALTH, CAIRO CITY, FOR THE YEAR 1923.

I.—Vital Statistics.

(a) *Population.*

The mid-year population of Cairo for 1923, as estimated by the Statistical Department, was 791,000, consisting of 721,429 Egyptians and 69,571 foreigners. To this population should be added that of the area around Helwân proper, which is administered by the inspectorate for all public health purposes, except the registration of births and deaths. This population, which has been estimated at 30,230, added to that of Cairo, amounts to 821,230.

(b) *Births.*

During 1923 the total number of births which occurred in Cairo was 41,309. Of this total 40,471 were Egyptian and 838 foreign births. The annual birth-rate was therefore 52·2 per thousand of population, as compared with 53·5 in the previous year.

(c) *Deaths.*

During 1923, a total of 28,806 deaths occurred in Cairo. Of these, however, 650 were deaths of non-residents, leaving 28,156 for Cairo proper.

This gives an annual death-rate of 35·6 per 1,000 of population, as compared with a rate of 34·3 for 1922.

(d) *Infantile Mortality.*

9,495 children under one year of age died during 1923, giving an infantile mortality of 230 per 1,000 births for the whole city, as compared with 239 in 1922 and 220 in 1921. In addition there were 227 deaths of infants coming from outside Cairo and who died in various public institutions.

During the quinquennial period ending with the present year the mean annual infantile mortality rate was 236 per thousand births.

The highest rate during this period was 255 in 1920 and the lowest 220 in 1921.

As regards the various districts of the city the lowest infantile mortality rate occurred in Ezbekiya with 181 infantile deaths per thousand births. Of the 9,495 deaths of children under the age of one year occurring in 1923, 9,410 were deaths of Egyptian infants and 85 of foreigners.

There is a tendency amongst the uninformed to take the view that because hygienic conditions are not better, the health authority is almost entirely to blame for the fearful infant mortality that prevails during the summer months. It is therefore of interest to note the following extract from an article entitled "Summer Diarrhœa in Infancy," by Dr. Pearson, of the Hospital for Sick Children, Great Ormond Street, London:—

Summer Diarrhœa in Infancy.

"The points of general agreement are that bad hygiene, bottle-feeding, and heat all have a positive influence in promoting the disease.

"Children in their first year are the chief sufferers, the highest mortality occurring in the last nine months of this period.

"Although bad hygiene and bottle-feeding exist at all times, yet diarrhœa is only prevalent in the hot months; hence we must regard a high temperature as a factor of great importance. The rise in mortality from diarrhœa occurring yearly in most cities, beginning in July and reaching its maximum in August or September, is very striking. Observations have shown that this increase occurs when the atmospheric temperature becomes sustained day and night above 60° F. (15·6° C.). An exact explanation cannot be given, but probably heat exerts its effect in several ways; first by depressing vitality thus lowering the power of resistance and lessening tolerance for food; and secondly, by favouring the growth of micro-organisms both within and without the body."

If such is the case in the cooler countries of Europe, infantile mortality in sub-tropical countries may always be expected to be very high during the hot season, however great the improvements that may be effected in hygiene. From the second week of May until the last week in October, the temperature did not fall below 15·6° C. The onset of the heat is accompanied by a very sudden enormous increase in infant mortality that decreases later on, although the temperature may still remain high. The most probable explanation of this is that ailing and weakly children at once fall victims and only the stronger children survive until the later summer months.

II.—Infectious Diseases.

The total for all infectious diseases reported during 1923 was 4,780 which includes 106 cases coming from outside Cairo, so that the total for Cairo proper was 4,674, as compared with 4,740 in 1922. Out of this total 3,189 with a mortality of 986 were cases belonging to the eight principal diseases. The remainder include 833 cases of influenza, 97

of whooping-cough, 106 of mumps, 24 of tetanus, 5 of Malta fever, 11 of encephalitis lethargica, 10 of rabies, 50 of puerperal fever, and 295 of chicken-pox. The rate per thousand of population for the eight principal diseases was 3,880, as compared with 3,165 in 1922, whilst the rate of deaths to cases was 30·9 per cent., as against 33·3 in the previous year.

Small-pox.—The total number of cases notified during the year was 28, as against 24 in the previous year. There were 13 deaths from this disease, 10 of which were diagnosed after death. All had been vaccinated, with the exception of one, which was only one month old.

Diphtheria.—The total number of cases recorded in 1923 was 1,418. There were 452 deaths from this disease, all of which were diagnosed after death, with the exception of one. This is an indication that a large number of cases of this disease was never declared but recorded.

Scarlet Fever.—There were 29 cases notified during the year, as compared with 68 in 1922, whilst the number of deaths from this disease was 3.

Diphtheria.—The total number of cases recorded in 1923 was 619, as compared with 418 in 1922. The total number of deaths was 194.

Typhoid Fever.—The total number of cases notified during the year was 969, as against 859 in 1922. The number of deaths from this disease was 242.

Typhus Fever.—The total number of cases recorded during the year was 112, which is the lowest total during the last 10 years. There were 77 deaths.

Relapsing Fever.—There were only 2 cases recorded this year and no deaths.

Cerebrospinal Fever.—There were twelve cases of this disease during the year, as compared with 8 cases in 1922. The number of deaths was 5.

Puerperal Fever.—The total number of deaths from puerperal fever during 1923 was 32, out of which 29 were among Egyptians and 3 among Europeans. There were, however, 28 deaths which occurred within a fortnight of confinement which, if added to the others, make a total of 60. The causes of these 28 deaths are given as: nephritis 1, eclampsia 9, hæmorrhage 4, peritonitis 3, abortion 1, enteritis 1, pneumonia 2, difficult labour 2, septicæmia 2, insanity 1.

Influenza.—The total number of cases notified during the year 1923 was 833, as against 1,461 in 1922. The number of deaths attributed to this disease was 21.

The number of deaths of all respiratory diseases, excluding pulmonary tuberculosis, was 4,423, out of which 1,871 were due to pneumonia, 2,388 to bronchitis, 26 to pleurisy and 138 to other respiratory diseases.

Of the 1,871 deaths from pneumonia, 1,322 were children up to 5 years of age, 154 from 5 up to 15, 166 from 15 up to 35, and 229 from 35 over.

Encephalitis Lethargica.—There were 11 cases notified during the year and the number of deaths from this disease was 6.

Plague.—Three cases of septicæmic plague occurred, the disease having been brought from Suez. Their history is as follows:—

(1) Boab came from Suez February 3, 1923, stayed with a friend, another boab, at Bab el Bahr, and died February 4. The medical officer who examined the body diagnosed tuberculosis.

(2) Boab, the host of No. 1, removed to Bâb el Sha'riya Qism and died on February 12, the death certificate from a private practitioner giving kidney disease as the cause of death.

(3) Brother of (2) died on February 16, the body was seen by the medical officer, who diagnosed typhus on the strength of a hæmorrhagic rash. Thanks, however, to the careful control exercised by the senior medical officer of the epidemic section, the inspectorate became aware of the case and specimens were taken and sent for bacteriological examination with the result that the case was proved to be plague. In the meantime every precaution had been taken and no further cases occurred.

There was also a case of bubonic plague imported to Cairo from Menouf Markaz, which died three hours after admission to the fever hospital.

Colonial Medical Reports.—No. 200.—Bengal.

ANNUAL REPORT OF THE MENTAL HOSPITALS IN BENGAL FOR THE YEAR 1924.

By Colonel R. P. WILSON, I.M.S.,

Surgeon-General with the Government of Bengal (offg.)

Accommodation.

The total capacity of all the mental hospitals in Bengal (including that of the mental observation ward at Bhowanipore and mental ward at the Albert Victor Leper Asylum at Gobra) that were in operation during the year 1924 was 1,147, as against 1,121 in 1923. The increase was due to the fact that the ward for Indian patients at Bhowanipore, which provides accommodation for 26 observation cases, was brought into use from May 1, 1924.

Population.

The total population of the two hospitals at Dacca and Berhampore and the mental ward at

Gobra was 1,172, as compared with 1,186 in the previous year. Their daily average strength was 977·05 (834·92 males and 142·13 females) as against 950·44 in 1923. The maximum number confined in any one night was 1,023 (878 males and 145 females) as compared with 973 in 1923. There was no overcrowding in any institution.

Admission and Readmission.

Altogether 224 insanes were admitted or readmitted during the year, as compared with 213 in the previous year.

The duration of insanity prior to admission was ascertained in 91 cases; it was less than three months in 28 cases, between three and six months in 13, between six and twelve months in 21, between one and two years in 12 and between three years and over in 17 cases.

Discharges and Recoveries.

The total number discharged during the year under report was 123, as against 157 in 1923; of this number, 85 were cured, as compared with 115 in the previous year, their percentage to daily average strength being 8·70, as against 12·09 in 1923. Of the 85 insanes cured, 38 suffered from mania, 6 from melancholia, 1 from circular insanity, 3 from delusional insanity, 4 from insanity due to alcohol, 10 from insanity due to cannabis indica, 22 from dementia præcox and 1 from idiocy.

Sickness and Mortality.

The general health of the patients at the time of their admission was better than it had been in 1923, their daily average sick having been 89·01, as against 116·97 in 1923. There was no outbreak of disease in epidemic form in the Dacca Mental Hospital; while at Berhampore a mild epidemic of influenza broke out in July, causing 63 admissions in the infirmary and only 1 death. The largest number of admissions in all the hospitals was from influenza, viz., 129 (66 at Dacca and 63 at Berhampore). The next highest number was 70 from diarrhœa. Dysentery accounted for 67 admissions and epilepsy for 52.

The mortality was much lower than in 1923, being 5·62 per cent. to daily average strength, as compared with 8·52 in 1923. The actual number of deaths was 55, viz., 12 at Dacca and 43 at Berhampore, as compared with 81 in 1923. Phthisis was the cause of death in 18 cases, senility in 9 cases, all occurred in the Berhampore Hospital. General tuberculosis was responsible for death in 7 cases and diarrhœa in 4 cases in all the hospitals.

Accidents and Injuries.

There was no accident or injury in the Dacca Mental Hospital. At Berhampore a serious accident occurred; a building situated in the outside garden of the hospital having collapsed during a severe hailstorm, a patient met instantaneous death.

There also occurred at Berhampore 7 cases of injury of serious nature, of which 5 were accidental and 2 inflicted by fellow-patients.

Escape.

There was 1 case of escape from the Bhowanipore Mental Observation Ward and 2 from the Berhampore Mental Hospital. A portion of the compound wall at Bhowanipore which was low afforded facility for the escape. This portion was raised to prevent further escapes. Of the two escapes at Berhampore one was captured and the other is still at large.

Observation Cases.

There were 104 cases under observation during the year, as against 63 in 1923; 65 of them were in the observation ward at Bhowanipore, 31 at Dacca, 6 at Berhampore and 2 at Gobra. Of these, 44 were certified as insanes and admitted into hospitals, 17 persons were released as uncertifiable, 33 persons, though certified as insanes, were released under Section 14, Act IV of 1912, 2 died and 8 remained at the end of the year.

Criminal Mental Patients.

There was a criminal population of 569 in the mental institutions, viz., 210 at Dacca, 356 at Berhampore and 3 at Gobra, as compared with 549 in 1923. Their daily average strength was 472·42, as against 453·97 in 1923. Sixty-two of them were discharged and 23 died. There remained, therefore, 484 criminal patients on December 31, viz., under trial 262, acquitted 140 and sentenced 82. Their crimes were murder in 214 cases, culpable homicide in 47, grievous hurt in 60, theft in 62, house trespass in 26 and other offences in 75 cases.

Private Patients.

Twenty private patients were admitted during the year 1924, as against 12 in the previous year, and 21 were remaining on January 1, 1924, as compared with 22 in 1923. Eleven were discharged, 2 died and 28 remained at the end of the year.

Finance.

The total receipts of the mental institutions (excluding those of the Gobra Mental Ward, for which no separate figures are available) amounted to Rs. 246,056, viz., Rs. 6,409 from fees of paying patients, Rs. 10,598 being the value of stores received from the manufacturing department, Rs. 200.413 being the receipts from the treasury and Rs. 28,636 being the book receipts. The corresponding figures for the preceding year were Rs. 317,228, Rs. 5,839, Rs. 8994, Rs. 215.654 and Rs. 86,741, respectively

The total expenditure amounted to Rs. 239,647, as compared with Rs. 311,389 in 1923. A smaller expenditure on buildings accounted for the decrease. The average annual cost per head of mental patients was Rs. 244-7-7, as against Rs. 327-3-9 in the year before.
